Although the effect of cycling a patient off PN has not been evaluated in clinical trials, this should be considered. Cycling PN, in which the infusion rate is gradually decreased to off for a period and then restarted and gradually increased to the desired rate, will decrease the length of time the liver is exposed to PN. VLBW infants, however, may become hypoglycemic even with very gradual decreases in infusion rate, so this option should be used with care. In any event, a short time off PN (eg, 2 hours) should be attempted.

The trace elements provided by the formulation should be examined. Both copper and manganese are enterohepatically

recycled and may accumulate in liver disease. Manganese can also contribute to hepatotoxicity and should be removed from J.H.'s PN solutions. Studies have not established when the removal of copper and manganese is warranted. The inappropriate removal of copper could lead to anemia, osteopenia, and neutropenia. Therefore, decreasing the copper dose and monitoring serum concentrations of both copper and manganese should guide therapy.

Current studies have demonstrated that omega-3 LCFAs, derived from fish oil, are the least inflammatory to the liver and can reverse the liver damage caused by PNALD. Fish oil is high in eicosapentaenoic and docosahexaenoic acids, which do not impair bile flow and may diminish fat accumulation in the liver. Omegaven®, an IV fat emulsion composed solely of fish oil, is U.S. Food and Drug Administration (FDA) approved for use in patients with established cholestasis; however, it has not shown efficacy in the prevention of PNALD in PN-dependent patients.[49] SMOF® (soybean oil [30%], medium-chain triglyceride [30%], olive oil [25%], and fish oil [15%]) a lipid, however, when initiated early in neonates requiring long-term PN has demonstrated a lower incidence of PNALD.[50,51] Other composite preparations that use a mixture of oil sources may still cause liver damage with long-term use but hold a theoretical benefit over pure soybean oil formulations in decreasing the risk of developing PNALD. Other research is being done using an oral formulation of fish oil in infants as a supplement to reverse PNALD.[52]

Pharmacologic interventions have had limited success in the management of PNALD. Phenobarbital has not been shown to be effective in reducing or reversing it.[53] Ursodiol 10 to 20 mg/kg/day has been used successfully in the treatment of other cholestatic liver diseases, and preliminary reports indicate that it may also improve PNALD in children.[54] Ursodiol, a naturally occurring nontoxic bile acid, presumably works by displacing and replacing the endogenously produced, potentially toxic bile salts that accumulate with cholestasis.

The antibiotic metronidazole also appears promising in the prevention of PNALD in adults. Metronidazole inhibits the bacterial overgrowth in the GI tract that occurs with intestinal stasis. The

bacteria are responsible for the increased formation of hepatotoxic bile acids such as lithocholate; 25 mg/kg/day of metronidazole has been shown to be effective.[55]

Case 103-7, Question 11: Project the course of J.H.'s liver disease if PN is discontinued and enteral feedings are instituted within 2 weeks. What may occur if enteral feedings cannot be instituted?

It is difficult to predict a successful wean from PN. Historically, success has been associated with longer length of intact small intestine. Additionally, studies in children with short bowel syndrome have shown that serum citrulline levels may predict the ability to successfully wean a patient from PN. Citrulline is a free amino acid that is produced by the small bowel enterocytes. Therefore, it may be warranted to measure J.H.'s serum citrulline level before weaning from PN.[56]

If PN can be discontinued soon after the onset of cholestasis, the prospects for J.H. to recover normal hepatic function are good. Jaundice usually resolves within 2 weeks after PN is discontinued, and the biochemical abnormalities normalize soon thereafter.[45] The pathologic changes observed on biopsy resolve even more slowly. Biopsy evidence of cholestasis has been observed for up to 40 weeks after resolution of clinical and serologic evidence of hepatic disease.[45]

If enteral feedings cannot be instituted successfully, the prognosis for J.H.'s liver function is not as good. Studies have demonstrated that infants receiving PN for 90 days or more had biopsy evidence of irreversible liver damage.[45] Thus, it is clearly advantageous to convert J.H.'s nutrition to the enteral route as soon as he tolerates such a change.

Common Pediatric Illnesses

Chephra McKee and Gildon Brooke

CORE PRINCIPLES		CHAPTER CASES
1	Medication administration to children can be challenging. For oral administration, dosing syringes or droppers should be used rather than household spoons or cups. The administration of medications by any route may require special techniques in an uncooperative child.	**Case 104-1 (Question 1)**
2	Diaper dermatitis presents as a mild red rash that often progresses to increased redness and lesions outside the diaper area. Barrier creams are recommended for initial treatment with the addition of a topical antifungal for dermatitis lasting >3 days and spreading outside the diaper area.	**Case 104-2 (Question 1, 2)**
		Case 104-3 (Question

3	Fever in children may be the result of a common viral infection but could also be an indicator of a more serious bacterial infection or lead to complications such as febrile seizures. Proper management depends in large part on accurate assessment.	**1, 2)**
4	The treatment of cough and cold symptoms in children younger than 6 years of age is generally supportive with nasal saline, hydration, and humidification. Over-the-counter agents have little proven effectiveness and have been associated with severe adverse effects owing to inadvertent overdoses during parental administration.	**Case 104-4 (Question 1)**
5	Constipation can be defined by a delay or difficulty in stooling for at least 2 weeks' duration. Constipation is most commonly functional and may be managed with behavioral modification or drug therapy.	**Case 104-5 (Question 1)**
6	Gastroenteritis, although usually self-limiting, may result in clinically significant dehydration in infants and children. Assessment of the degree of dehydration is important in determining whether oral rehydration is appropriate or hospital admission with intravenous rehydration is required.	**Case 104-6 (Question 1–3)**
7	Gastroesophageal reflux is a common	**Case 104-7 (Question 1, 2)**

	disorder in young infants. Most will require no intervention. Some, however, will require feeding modifications and, possibly, drug therapy, including acid-suppressing or prokinetic agents.	
8	Otitis media is a middle ear infection associated with effusion, rapid symptom development, and evidence of middle ear inflammation. Options for therapy include antibiotic management and watchful waiting, the choice of which depends on the age of the child and severity of the disease. Amoxicillin (or amoxicillin/clavulanate) remains the antibiotic of choice despite the high incidence of penicillin–nonsusceptible *Streptococcus pneumoniae*.	**Case 104-8 (Question 1–3)**
9	Acute pharyngitis may be caused by respiratory viruses or bacteria, most commonly *S. pyogenes*. Treatment goals for bacterial pharyngitis include resolution of symptoms and prevention of rheumatic heart disease. Amoxicillin is the antibiotic of choice for bacterial pharyngitis.	**Case 104-9 (Question 1, 2)**

INTRODUCTION

Children represent nearly a quarter of the U.S. population. From 2011 to 2014, 21.9% of all U.S. children used a prescription medication in the prior month, with 8.5% taking two or more medications.[1] The most commonly used medication classes include

asthma medications, antibiotics, attention deficit hyperactivity disorder (ADHD) medications, topical agents, and antihistamines. In addition, medication errors have been found to occur more frequently in children than in the adult population.[2] Given the prevalence of medication use in children, it is essential that health care providers be prepared to educate families and children on the appropriate use of medication therapy.

ADMINISTERING MEDICATION TO CHILDREN

CASE 104-1

QUESTION 1: M.B., a 16-month-old female weighing 19.84 pounds (9 kg), has been diagnosed with an ear infection. She will be receiving amoxicillin (400 mg/5 mL) 5 mL by mouth every 12 hours.

What tips for successfully administering these medications should be recommended?

Oral Medications

The administration of oral medications to a young child or an infant often requires two adults: one to gently restrain the child while the other rapidly and accurately administers the medication. If only one adult is available, restrain the arms and legs of the child in a swaddling blanket or large towel, as depicted in **Figure 104-1**.

Figure 104-1 Administration of oral liquid medication to a young child. (a) Premeasure the medication and have it within reach. (b) Hold the child in your lap, placing one of the child's arms behind your back and both of the child's legs between your legs. Restrain the child's other arm securely with your nondominant arm. (c) Tilt the child's head back slightly, pressing gently on the child's cheeks to open the mouth. Using your dominant hand, aim the dropper or syringe between the rear gum and cheek. Administer small amounts of medication (1–2 mL) at a time, making sure the baby swallows.

The administration device (syringe, dropper, or dosing spoon) that generally accompanies a liquid medication product provides the most accurate measurement of the desired dose. For infants, liquid medications are most easily administered to the back cheek in 1- to 2-mL amounts with an oral syringe. Household teaspoons should not

be used to measure medications because teaspoons are of variable sizes and hold 3 to 8 mL of a liquid. Other considerations involve the unit of measurement. To decrease errors and improve the precision of drug delivery, it is recommended to use milliliter-based dosing exclusively while prescribing and administering liquid products.[3]

In some situations, crushed tablets or capsule contents mixed in small amounts (1–2 tsp) of food (eg, chocolate pudding, applesauce, ice cream, jelly, and chocolate syrup) offer an alternative to liquid formulations. The taste of liquid dosage formulations is generally improved by refrigeration and flavoring agents, and “chasers” (ie, popsicle, chocolate syrup, or a flavored drink after a dose) are also helpful. Although medications can be delivered in small amounts (10–15 mL) of liquid in a bottle (juice, milk, and formula), doses should not be diluted into an entire scheduled feeding or prepared ahead of time in batches in anticipation of future administration. Limiting the volume more likely facilitates delivery of the entire dose, and adding the medication to a feeding bottle immediately before delivery minimizes the potential of drug instability. Drug interactions with foods and dairy products should also be considered before drugs are added to feeding formulas. Most children are able to swallow tablets at ages 5 to 8 years. Parents should ask the pharmacy to split the prescription into two bottles to assist in supplying medications to the school when midday doses are required for children during school hours. Children of all ages should be encouraged and praised for their cooperation in taking their medicine. Rewards and positive reinforcements can be useful to gain cooperation in an older child.

For M.B.’s amoxicillin, the parents should be given a dosing syringe and shown how to measure 5 mL. If M.B. is uncooperative with medication administration, she may need to be restrained and the medication delivered in 1- to 2-mL increments. The parents should be ready to provide M.B. with something that tastes good immediately after administering the medication.

Ear, Nose, and Eye Drops

Otic, ophthalmic, and nasal medications usually need to be administered to infants and young children in a manner different from that used in adults. Otic medications should be instilled by pulling the auricle down and out in infants and young children, whereas older children should have the auricle of the ear held up and back to straighten the ear canal. During the instillation of nose and eye drops, position infants and toddlers with their head lower than the rest of the body because gravity assists in dispersing the medication. This can be achieved by laying the infant across a bed with the shoulders projecting over the edge of the bed. Restraining the infant often is required during the administration of ophthalmic formulations. When administering the eye medication (**Fig. 104-2**), the caregiver must be cautious to avoid injury to the eye caused by sudden movements of the infant. The technique of placing the hand, which holds the eye medication on the forehead of the infant during administration, can help minimize eye injury because the hand holding the eye dropper will move when the infant's head moves.

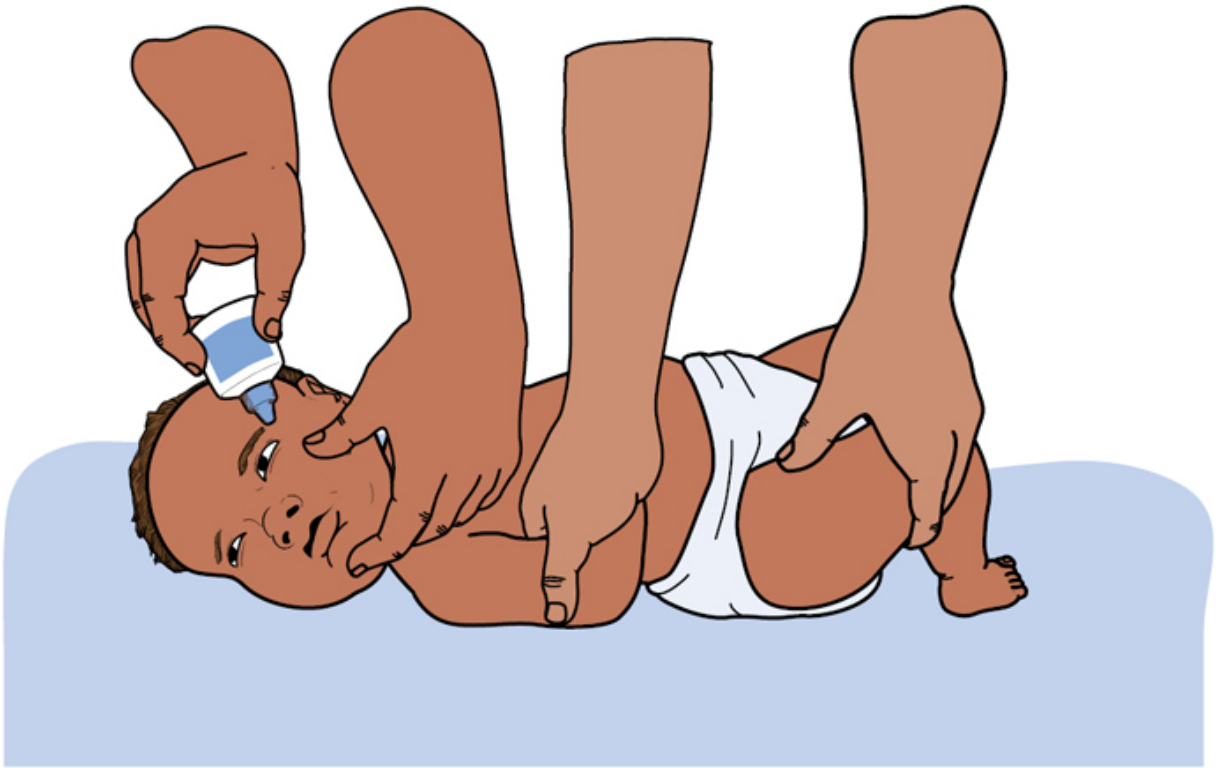

Figure 104-2 Administering eye drops to a young child. (a) Place the child on a flat surface. Enlist the help of a second adult to restrain the child or swaddle the child. (b) Holding the child's head steady, gently pull the eyelids apart. The hand that is holding the medication dropper can rest on the child's head while administering the medication to minimize the potential for injury to the eye if the child's head moves abruptly. Administer the medication as directed.

To minimize fear and improve cooperation during instillation of eye, nose, or ear drops, the procedure should be explained to the child as simply as possible. It is best to warm the medication in your hand for a few minutes before administration because medications can feel cold inside the ears or nose even when stored at room temperature.

If ear drops were to be administered to M.B., she should be lying down with the affected ear up. The auricle should be pulled down and out, and the ear drops placed in the ear canal. She should remain in that position for at least 1 minute.

PEDIATRIC CARE

Diaper Rash

ETIOLOGY

Diaper dermatitis (DD) is commonly encountered in pediatric practice. Although the pathogenesis of DD is not well defined, a number of factors (eg, chemical irritants, friction, and bacteria) have been associated with skin inflammation in the diaper area. In particular, skin wetness and pH have been implicated in DD. Overhydration contributes to impaired barrier function by breakdown of the stratum corneum structure.[4] This is further exacerbated by the effects of friction. Diaper design and performance also play a role in DD. Diapers, either cloth or disposable, with plastic outer linings decrease air circulation and increase moisture in the diaper area and

should be avoided. Residual chemicals or laundry detergents in the diaper, as well as soaps, medications, or lotions that have been applied directly to the infant's skin, also have a role in the development of diaper rash.

CLINICAL PRESENTATION

Four clinical presentations of dermatitis are associated with diaper wear:

1. A mild, scaling rash in the perianal area
2. A sharply demarcated confluent erythema
3. Ulceration distributed through the diaper area
4. A beefy red confluent erythema with satellite lesions, vesiculopustular lesions, and diffuse involvement of the genitalia

TREATMENT

CASE 104-2

QUESTION 1: K.G., a 3-month-old infant, has had a severe diaper rash for the past 4 days. The very inflamed and tender area is confined to the diaper area, and vesicular satellite lesions are present on the periphery of the erythematous area. K.G.'s mother uses only cloth diapers and has not changed her soap or her normal pattern of diaper care since K.G. was born.

What is the likely cause of K.G.'s diaper rash and what treatments are appropriate?

K.G.'s rash is consistent with a *Candida* infection, which typically is beefy red and associated with vesicular satellite lesions. The presence of a rash for >3 days and the diffuse involvement of the genitalia and inguinal folds are also characteristic of this form of diaper rash. K.G.'s rash can be treated with clotrimazole 1% cream, miconazole 2% cream, or nystatin 100,000 units/g ointment applied to the inflamed area two to four times daily until it has resolved.[5]

Case 104-2, Question 2: What steps would you recommend for K.G.'s mother to treat her diaper rash and prevent recurrence?

The removal of stool and urine from the diaper area by gentle rinsing with plain water and more frequent diaper changes often help alleviate diaper rashes. Wiping the baby with diaper wipes that contain alcohol can sting, further irritating the involved area, and should be avoided until the rash has resolved. A good protective agent containing zinc oxide or petrolatum can be applied with each diaper change to create a barrier to irritants and seal out moisture. Other prevention and treatment measures appropriate for K.G. include the following:

1. Change the diaper as soon as it is wet or at least every 2 to 4 hours during the day.
2. Keep the diaper area clean (eg, nightly baths until resolved).
3. Use superabsorbent disposable diapers at night.
4. Expose the diaper area to air as often as possible.
5. Dry the diaper area completely before a new diaper is put on.
6. Apply a barrier cream such as zinc oxide or petrolatum after each diaper change.
7. For cotton diapers, use a bacteriostatic agent in the diaper pail and rinse water or use a diaper service to ensure that diapers are sterile.
8. Apply a low-potency, nonfluorinated topical corticosteroid, such as hydrocortisone 0.5% to 1%, twice daily for no longer than 1 to 2 weeks when severe inflammation is present.[4]

Fever

Normal body temperature varies throughout the day, peaking in the late afternoon or early evening.[6] Body temperature can be measured rectally, orally, axillary (under the arm), temporally (on the forehead), and tympanically. Rectal temperatures are most reliable in infants

younger than age 3 months. Oral measurements of temperature are not appropriate in children younger than age 3 years because it is difficult for young children to maintain a tight seal around the thermometer.

Although references differ, fever can be defined as an axillary temperature >99.4 °F (37.4 °C) or a core temperature >100.4 °F (38 °C).[7] Normal temperature ranges for rectal and tympanic measurements are typically 0.5 to 1 °F (0.3–0.6 °C) higher than an oral or a temporal reading, whereas axillary measurements are slightly lower.

Children with fevers might not have other signs or symptoms of an illness. Any child younger than age 3 months who develops a fever requires a complete evaluation (eg, blood culture and urinalysis) because clinical manifestations of a serious infection often are subtle, nonspecific, and/or not predictive of the extent or severity of illness.[6] In this situation, antibiotic therapy may be initiated while awaiting laboratory results.[8] Concerns of fever in children ages 3 to 36 months exist (eg, bacteremia), yet there is a greater variability in clinical practice regarding empiric testing and treatment.[6] Children of any age with a temperature >104 °F (40 °C) should be evaluated irrespective of accompanying symptoms.[7] Febrile immunocompromised children and febrile children with functional or anatomic asplenia are at increased risk for sepsis or fulminant infections (eg, *Streptococcus pneumoniae*, *Salmonella* species, and *Escherichia coli*) and should receive prompt antibiotic therapy.[6]

CASE 104-3

QUESTION 1: R.B., a 12-month-old, 22.05-pound (10-kg) male, was well yesterday until his mother noticed that he felt warm to her touch later in the afternoon. For the past 24 hours, he has remained warm and is fussy and less active. A rectal temperature 15 minutes ago was 102.2 °F (39 °C). Because her other two children experienced febrile seizures, his mother is concerned that R.B.'s temperature will continue to rise and put R.B. at risk for febrile seizures.

Is this a valid concern?

Febrile seizures occur in ~2% to 5% of children 6 months to 5 years of age who have temperature elevations >100.4 °F (38 °C).[9] The exact etiology and pathogenesis are unknown, yet it has been found that the height in temperature rather than the speed of temperature rise is the greatest risk factor for febrile seizure development.[9] Genetic predisposition also appears to be a factor because febrile seizures occur with greater frequency among family members.[9] Febrile seizures are of two types: simple and complex. Simple febrile seizures last <15 minutes and do not have significant focal features. Complex febrile seizures have a longer duration, occur in series, and are associated with focal changes. Typically, febrile seizures occur within the first 24 hours of a febrile episode.[9] Although R.B. is in the age group at greatest risk for having a febrile seizure and he has a genetic link based on his family history, he has been febrile for >24 hours, and a seizure is unlikely during this illness.

TREATMENT

Case 104-3, Question 2: How should R.B.'s fever be treated?

Acetaminophen is the most common antipyretic agent used in children. The usual dose, oral or rectal, is 10 to 15 mg/kg/dose administered every 4 to 6 hours as needed to a maximum of 5 doses or 75 mg/kg/day, not to exceed 4000 mg/day.[10,11] Ibuprofen is administered as 5 to 10 mg/kg/dose orally every 6 to 8 hours as needed to a maximum of 40 mg/kg/day. Ibuprofen is as effective as acetaminophen as an antipyretic and is similar in safety.[11] Although renal failure has been reported after ibuprofen use in children, the risk of renal impairment appears greater in children with dehydration, underlying cardiovascular or renal disease, or other nephrotoxic drugs, and children age older than 6 months.[11] The American Academy of Pediatrics (AAP) recommends that ibuprofen not be used in the first 6 months of life owing to unknown effects on the developing kidney.[11]

Acetaminophen 100 to 150 mg every 4 to 6 hours as needed or ibuprofen 50 to 100 mg every 6 to 8 hours as needed should be effective in lowering R.B.'s fever. Acetaminophen is formulated in a liquid dosage form (children's suspension, 160 mg/5 mL) and in various chewable tablet strengths targeted at pediatric patients. At recommended doses, acetaminophen is regarded as safe. Yet, it is imperative to counsel caregivers to avoid concurrent use of any other products containing acetaminophen to avoid potential hepatotoxicity.[11] Further data for the treatment of fever suggest that ibuprofen may be a more effective alternative to acetaminophen for R.B. because ibuprofen seems to have a longer clinical effect related to lowering the body temperature.[11] It is available in two liquid formulations (infant drops, 40 mg/mL; children's suspension, 100 mg/5 mL) and a chewable tablet. Adverse effects are limited when ibuprofen is used in recommended doses for short-term antipyresis. Some data suggest that combination therapy with acetaminophen every 4 to 6 hours and ibuprofen every 6 to 8 hours may be more effective in reducing time with fever in the first 24 hours.[11] However, combination therapy may be associated with medication errors and negative safety outcomes.[11] Owing to the safety risk without a clinically significant benefit, alternating or combination therapy is not suggested. Aspirin therapy is not recommended for the treatment of fever in children or adolescents with chickenpox, gastroenteritis, or respiratory viral infections because of its link with Reye syndrome.[10,11]

Cough and Cold

Another common diagnosis in children is a viral upper respiratory infection or the common cold. Preschool children generally experience between six and eight colds each year.[12] Children with a cold often present with sore throat, nasal congestion, rhinorrhea, sneezing, cough, and irritability.

CLINICAL PRESENTATION AND TREATMENT

CASE 104-4

QUESTION 1: J.K. is a 3-month-old, 11.68-pound (5.3-kg) infant who began having nasal congestion, rhinorrhea, and cough yesterday. She has had no fever and is eating well but did not sleep well last evening. J.K.'s mother called her pediatrician and was told that J.K. most likely has a cold caused by a virus. Which cold medications would be appropriate to manage J.K.'s symptoms?

A cool-mist humidifier can increase the amount of moisture in room air and decrease irritation in the upper airway when humidity is low. Saline nose drops followed by suctioning can help clear the nasal passages in J.K. who is younger than age 6 months. It is especially important to do this before feedings. A decongestant, however, should not be prescribed for J.K. because of her age and the potential for adverse effects. If J.K. was older and a topical nasal decongestant was needed, phenylephrine would be preferred. Antihistamines, antitussives, nor guaifenesin should be recommended for J.K. because there is no evidence of efficacy, and unintentional overdoses are common in this age group. Antihistamines are not effective for rhinorrhea caused by the common cold and should not be recommended. Antitussives are likely not effective and should not be used if the child's cough is productive. Expectorants, such as guaifenesin, are also not effective, and evidence is insufficient to support the use of vitamin C, zinc, or echinacea in children for treatment or prevention of the common cold.

Several hundred over-the-counter (OTC) medications for upper respiratory symptoms are available, and >1 billion units of these products are sold each year in the United States.[13] Nevertheless, the safety and effectiveness of these cough and cold medications in children have yet to be proved.[14] The Centers for Disease Control and Prevention (CDC) reported that 1519 children younger than age 2 years were admitted to emergency departments in 2004 to 2005 because of overdoses and other problems associated with cough and cold medicines. Furthermore, according to the U.S. Food and Drug Administration (FDA), 54 deaths in children were linked to the use of decongestants (eg, pseudoephedrine, phenylephrine, and

ephedrine) and 69 deaths to antihistamines (eg, diphenhydramine, brompheniramine, and chlorpheniramine) from 1969 to September 13, 2006. Most of these deaths occurred in children younger than age 2 years, and some of the fatalities occurred in children who received overdoses that might have been the result of inadvertent administration of multiple medications containing the same ingredient.

In 2008, the FDA issued a public health advisory recommending that OTC cough and cold medications not be used in children younger than age 2 years.[15] Later that year, the Consumer Healthcare Products Association announced that many manufacturers would voluntarily modify their labels to exclude recommendations for children younger than age 4 years.[16] Owing to reports of toxicity and death related to OTC cough and cold products, the CDC has recommended that caregivers avoid giving these products to children younger than age 2 years unless advised by a clinician.[14] If deemed necessary by a physician for older children, nonprescription cough and cold medications containing single ingredients should be selected to minimize the potential for adverse effects and administration of multiple products with similar ingredients. Of note, parents often misunderstand labeling of OTC products, placing the child at risk for dosing errors.[17] It is critical that health care providers educate caregivers on the proper use and administration of these medications to children. Treatment of J.K.'s symptoms should include the use of a cool-mist humidifier in the room and saline nasal drops followed by suctioning before feedings.

Constipation

Chronic constipation is defined as delay or difficulty in stooling for at least 2 weeks' duration.[18] It accounts for 3% of annual visits to pediatrician offices and up to a quarter of referrals to gastroenterologists.[19] Beyond the neonatal period, constipation is most commonly idiopathic or functional and may be related to a diet low in fiber, lack of time or routine for toileting, or passage of a

painful stool resulting in fear of defecating. Other causes of constipation include anatomic (fissures), neurogenic (Hirschsprung disease), hypotonic (cerebral palsy), and endocrine (cystic fibrosis and hypothyroidism) disorders.[19] Medications such as opioids, antacids, and anticonvulsants, among others, can also contribute to constipation. It is important that constipation be managed appropriately because it can have negative effects on growth and development, has been linked to gastrointestinal (GI) distress, and adversely impacts the quality of life.[19]

CLINICAL PRESENTATION AND TREATMENT

CASE 104-5

Question 1: R.J., a 2-year-old, 33.06-pound (15-kg) male, has had abdominal pain for 4 weeks. On average, he has one stool weekly, and he cries each time because of pain. R.J. eats regular table food and has two glasses of whole milk each day. After obtaining a thorough history and performing a physical examination, the physician determines that R.J. has functional constipation.

What treatment measures are appropriate to relieve and prevent R.J.'s constipation?

Before maintenance therapy can be initiated, disimpaction of the patient is necessary. Although no controlled studies compare the efficacy of the oral and rectal routes, oral therapy (mineral oil, polyethylene glycol, and bisacodyl) is preferred because it is less invasive and might lead to better adherence than does rectal therapy (phosphate soda enemas, mineral oil enemas, glycerin suppositories in infants, and bisacodyl suppositories in older children).[19] After disimpaction, a combination of behavioral, dietary, and pharmacologic therapies should be initiated to promote regular stool production and prevent reimpaction. Dietary interventions include adequate fluid and fiber intake. Medications such as polyethylene glycol 3350, mineral oil, lactulose, and sorbitol should be titrated to produce one to two soft stools daily. Stimulant laxatives might be needed intermittently in certain cases. Although no clear recommendation for one maintenance medication has been given

over others, recent data suggest that polyethylene glycol may be the most effective and best tolerated in children.[19] The recommended dosing of medications for the treatment of constipation is listed in **Table 104-1**. Appropriate initial therapy for R.J. could include limiting milk intake, increasing water intake, behavioral techniques, and polyethylene glycol 0.5 to 1.5 g/kg/day (7.5–15 g). Practically, this would be half to one 17-g packet administered daily in 4 to 8 oz of water or other beverage.

Table 104-1

Medications for the Treatment of Constipation

Medication	Initial Dosage	Comments
Osmotic Agents		
Polyethylene glycol 3350	0.2–0.8 g/kg/day	0.5 g/kg initial dose; titrate to effect; do not exceed 17 g/day.
Lactulose	1–2 g/kg/day divided once or twice daily	1.5–3 mL/kg/day; do not exceed 60 mL/day.
Sorbitol	1–3 mL/kg/day once or twice daily	Less expensive than lactulose
Barley malt extract	2–10 mL/240 mL of milk or juice daily	Useful for infants drinking from a bottle
Magnesium hydroxide	1–3 mL/kg/day using 400 mg/5 mL	Infants are at risk for hypermagnesemia.
Phosphate enema	≥2 years: 6 mL/kg up to 135 mL	Electrolyte abnormalities more common in children with renal failure or Hirschsprung disease. Avoid in children > 2 years.
Lubricant		
Mineral oil	>1 year: disimpaction: 15–30 mL/year of age up to 240 mL daily	Better tolerated if chilled. Avoid in children >1 year. Lipoid pneumonia may occur if aspirated.
	Maintenance: 1–3 mL/kg/day	Maximum daily dose: 90 mL/day
Stimulants		

Medication	Initial Dosage	Comments
Senna	2–6 years: 2.5–5 mg/day	Not recommended for chronic use
	6–12 years: 7.5–10 mg/day	
	>12 years: 15–20 mg/day	
Bisacodyl	3–10 years: 5 mg/day	Not recommended for chronic use
	>10 years: 5–10 mg/day	
Glycerin suppositories	2–5 years: 1 pediatric suppository per dose	Preferred stimulant for children >2 years
	≥6 years: 1 adult suppository per dose

Vomiting and Diarrhea

Vomiting and diarrhea, two commonly encountered problems in pediatric practice, are usually self-limiting, but severe cases can result in serious complications such as dehydration, metabolic disturbances, and even death. Infants and young children are particularly susceptible to more severe complications.

PATHOGENESIS AND PRESENTATION OF VOMITING

Vomiting or emesis is defined as forceful expulsion of GI contents through the mouth or nose, whereas nonforceful expulsion of GI contents is considered as regurgitation. In newborns, regurgitation of small amounts of breast milk or formula after feeding, especially when burping, is common. In most cases, regurgitation usually resolves by age 1 to 2 years and rarely causes problems.[20]

Extensive evaluation of regurgitation is not needed in a child who is growing well. Other causes of vomiting during the newborn period include pyloric stenosis, gastroesophageal reflux (GER), overfeeding, food intolerance, and GI obstruction. Beyond the neonatal period, the most common cause of vomiting is infection. Vomiting in infants and children can also be caused by central nervous system (CNS) disease (eg, intracranial tumors), metabolic disease (eg, urea cycle disorder), inflammatory bowel disease, and ulcers. Conditions causing emesis in older infants and children range from viral gastroenteritis to more severe illnesses, such as bowel obstruction or head injury, which require immediate medical attention.[21] Acute vomiting can also result from medication or toxic ingestions. In teenagers, migraine, pregnancy, and psychological disorders, such as bulimia, have been associated with vomiting.

PATHOGENESIS AND PRESENTATION OF DIARRHEA

Diarrhea refers to an increase in frequency, volume, or liquidity of stool when compared with normal bowel movements. In developing countries, diarrhea is a common cause of death in children younger than age 5 years. In the United States, gastroenteritis accounts for ~1.5 million physician visits, ~200,000 hospitalizations, and about 300 deaths each year.[22]

Acute diarrhea in infants and children is generally abrupt in onset, lasts a few days, and is most commonly caused by viruses. (See Chapter 69, Infectious Diarrhea for infectious diarrhea of other origins.) Diarrhea is considered chronic if it is >10 g/kg/day in toddlers/infants or 200 g/day in older children lasting >4 weeks in duration.[22] Persistent diarrhea may begin acutely but lasts >14 days.[23] Chronic diarrhea can be caused by malabsorption, inflammatory disease, infection, alteration of intestinal flora, milk or protein intolerance, drugs, and other causes.[23]

Infants and children are at high risk for morbidity and mortality secondary to diarrhea for several reasons. Dehydration can occur easily because acute net intestinal fluid losses are greater in young children than in adults. This may result from inefficient transport

systems in the developing intestine. In addition, the percentage of total body water in children is higher than that in adults; thus, they are more susceptible to body fluid shifts. Total body water changes from 80% of total body weight in premature infants to 70% in term infants and 60% in adults.

VIRAL GASTROENTERITIS

CASE 104-6

QUESTION 1: J.R., a 15-month-old male 22.05-pound (10-kg) infant, had one loose stool and began vomiting this morning, but he has not had a fever. On questioning, you discover that many children attending day care with J.R. are experiencing vomiting, diarrhea, and low-grade temperatures.

How should J.R.'s vomiting be treated?

Routine use of antiemetics for acute vomiting in children is not recommended because masking of symptoms may delay the diagnosis of a treatable illness. In addition, the safety and efficacy of the antiemetics, including metoclopramide, promethazine, trimethobenzamide, and dimenhydrinate, have not been demonstrated.[22] In particular, promethazine is contraindicated in children younger than age 2 years because of the risk of fatal respiratory depression. Ondansetron does decrease vomiting, increases oral intake, and decreases the need for intravenous (IV) rehydration; however, the utility of ondansetron in gastroenteritis needs consideration because this effect may not be sustained and has been shown to increase the risk of diarrhea.[22]

Parents should be taught the signs and symptoms of gastroenteritis and vomiting that are sufficiently serious to warrant medical attention. The child's primary care provider should be contacted if the child is toxic appearing, exhibits unusual behavior, exhibits signs of an ear infection, experiences abdominal pain or distension, has red or black vomitus or stool, or if there is a history or

suspicion of toxic ingestion or head trauma. Medical evaluation is also necessary for infants younger than 6 months of age, when persistent vomiting or high-volume diarrhea is present or when chronic medical conditions or prematurity is involved. Because fever can accompany vomiting in viral gastroenteritis, any fever occurring in a neonate warrants medical attention. Fever in older infants and children warrants medical attention when it becomes prolonged or there are changes in pattern.

When communicating with a health care provider about a vomiting child, it is helpful if the parents have knowledge of the child's fluid intake and the frequency and volume of vomiting and urination. The amount of vomitus can be estimated by the following rule of thumb: 1 tbsp makes a spot 4 inches wide and a quarter cup makes a spot ~8 inches wide.

Vomiting associated with gastroenteritis usually resolves in 24 to 48 hours. Infants are particularly susceptible to the development of fluid and electrolyte abnormalities; therefore, fluid and electrolyte replacements are critically important.

J.R., who is early in the course of gastroenteritis, must receive sufficient fluids to prevent dehydration. Oral hydration therapy can be successful when given in small volumes, even if J.R. is still vomiting. For example, 5 to 10 mL can be administered every 5 to 10 minutes, with gradual increases in volume as tolerated. Volumes equal to the estimated fluid deficit (usually 50–100 mL/kg) should be given over the course of 2 to 4 hours. For each diarrheal stool, an additional 10 mL/kg of oral electrolyte solution should be given. If diarrhea or vomiting recurs, 10 and 2 mL/kg of an oral rehydration solution (ORS) can be administered for each stool or emesis, respectively.[24] J.R.'s clinical condition should continue to be monitored by his caregiver. If stool output >10 mL/kg/hour, ORS might not be sufficient, and the health care provider should be contacted. ORS should only be abandoned in children with intractable vomiting, loss of consciousness, bowel obstruction, or if the child is in shock. Most infants will tolerate oral hydration when small amounts are given frequently. As dehydration is corrected, the frequency of vomiting typically decreases. Once rehydration has been achieved, fluids

other than ORS and a diet appropriate for age may be started.[24] Breast milk or formula should be given as tolerated.

Assessment of Dehydration

Case 104-6, Question 2: On the second day of illness, J.R. develops a mild fever and diarrhea that has increased in frequency and water content. How can the severity of J.R.'s diarrhea be assessed?

To determine the severity of dehydration and whether hospitalization may be needed, consider the following questions:

1. Does the child have any of the following signs and symptoms of severe dehydration: deeply sunken eyes, parched mucous membranes, significantly prolonged capillary refill; cool, mottled extremities; crying without tears; oliguria or anuria; weak or thready pulses; lethargy; poor oral intake; deep respirations; history of seizures or convulsions; a fever without perspiration; or thirst?
2. Are a large number of copious stools still being produced (>10 mL/kg/hour)? Is bowel obstruction a possibility?
3. Is there a risk of dehydration from inadequate monitoring, or is the parent unable to care for the child? Specific inquiries should be made about the number and consistency of stools in children with diarrhea.

Estimating the degree of dehydration is particularly valuable in assessing the patient with diarrhea, and weight loss is a good criterion. A 3% to 9% weight loss is considered mild-to-moderate dehydration, whereas >9% is considered severe dehydration.[24] (See Chapter 103, Pediatric Fluid, Electrolytes, and Nutrition, for information about IV replacement therapy in children with ≥10% dehydration.)

Oral Replacement Therapy

Case 104-6, Question 3: J.R. was evaluated by his pediatrician and was not considered to be sufficiently dehydrated to warrant hospitalization. How might J.R.'s fluids and electrolytes be managed on an outpatient basis?

The goal of J.R.'s treatment should be focused on the prevention of dehydration and the restoration and maintenance of adequate fluid and electrolyte balance. Mild-to-moderate diarrhea without dehydration is generally managed at home by continued age-appropriate feeding. Fluid losses in stools can be replaced with a glucose-containing ORS. Glucose provides calories and enhances salt and water absorption in the small intestine through mechanisms that are usually unimpaired in many toxin-induced diarrheas. Commercially available oral glucose–electrolyte formulations, such as Pedialyte®, are designed to enhance glucose and sodium absorption and should be used in infants and young children. Carbonated beverages and fruit juices do not contain sufficient sodium to replace diarrheal losses and should not be used. Rehydration and maintenance solutions can be made more palatable with sugar-free flavorings (eg, Kool-Aid® and Crystal Lite®).

The World Health Organization (WHO) original formula, which had a 90% successful rehydration rate for the management of diarrhea, contained a high concentration of sodium. Although commercially available ORSs contain less sodium than does the WHO formulation, these preparations were equally effective as the WHO formula, even when used to treat the high-sodium losses associated with cholera. Furthermore, these lower sodium-containing formulations were associated with less vomiting, lower stool output, and reduced need for IV infusions in non–cholera-associated gastroenteritis. As a result, the WHO, in 2002, promoted a formulation that consists of 75 mEq/L sodium and has a total osmolarity of 245 mOsm/L.[24] The electrolyte content of commonly used ORS is provided in **Table 104-2**. Assuming J.R.'s fluid deficit is 50 to 100 mL/kg, he should receive 500 to 1000 mL of ORS in the course of ~4 hours. In addition, he should receive an extra 100 mL for each diarrheal stool and 20 mL for each emesis that occurs. If stool output continues at a pace that cannot be matched with oral replacement, or signs and symptoms of

severe dehydration occur, J.R. should be referred to his pediatrician again.

Table 104-2
Oral Electrolyte Solutions

Solution	Compositions			
	Sodium (mmol/L)	Potassium (mmol/L)	Carbohydrate (g/L)	Osmolality (mmol/L)
Rehydration

REINSTITUTION OF ORAL FEEDINGS

Previously, feeding during an episode of viral gastroenteritis has been delayed because of the malabsorption that typically occurs during and after these bouts. The malabsorption, however, is self-limiting, and substantial amounts of carbohydrate, protein, and fat can still be absorbed. The reinstitution of a regular diet, therefore, should not adversely affect mild diarrhea and can be beneficial.[24] Parents are encouraged to continue feeding their children using age-appropriate diet while avoiding foods high in fat and simple sugars. Specific diets are often recommended during diarrhea (eg, BRAT [bananas, rice, applesauce, toast]). Although these diets can be occasionally useful, the nutritional value of these foods is relatively low, and they do not provide optimal nutrition compared with complete diets with fats and proteins.[24] Once J.R. has been adequately rehydrated, he may resume his normal diet. However, the caregivers must take care to avoid juices and other foods with simple sugars, which may worsen diarrhea.

Drug Therapy

Medications play a minor role in the treatment of acute infectious diarrhea because most episodes are self-limiting. Antibiotics are recommended when systemic bacteremia is suspected, when immune defenses are compromised, when a persistent enteric infection is sensitive to antibiotics, or in certain clinical situations when *Shigella*, *Campylobacter*, *Clostridioides difficile*, and *Salmonella* strains are isolated.[25] In general, antidiarrheal preparations are not recommended for infants or children because they have little effect on acute diarrhea, are associated with side effects, and direct attention away from the use of oral hydration therapy.[22] Drugs such as loperamide that alter GI motility should be avoided, especially in children with high fever, toxemia, or bloody mucoid stools, because they may worsen the clinical course of the bacterial infection.

Probiotics, live microbial products containing species of *Lactobacillus*, *Bifidobacterium*, *Saccharomyces*, and *Streptococcus*, can improve the balance of intestinal flora and diminish the effect of enteric pathogens. These microbes are thought to exert their beneficial effects through various mechanisms, including producing antibacterial chemicals, competing with enteric pathogens, inhibiting the adhesive capabilities of pathogens, altering toxins or toxin receptors, and upregulating interleukin-mediated T-cell response.[22] Probiotics are most useful in viral gastroenteritis when used early in the course of the disease. Lactobacilli are the most well-studied species and have been the most consistently effective in clinical trials. It appears that the efficacy of the different species may depend on the specific strain, the dose, and the timing of administration.[22] The manufacture of probiotics is not regulated by the FDA; therefore, the organism count per dose might be based on the number present at the time of production and not at the time of expiration, and the labeling might incorrectly identify the species of organism. For J.R., a *Lactobacillus* preparation administered for 5 days may provide some modest clinical benefit, although the benefit is most pronounced in rotavirus diarrhea, which has not been documented in his case.

GASTROESOPHAGEAL REFLUX

GER is a common disorder, with infants experiencing recurrent vomiting and regurgitation that peaks during the first 4 months of life.[20] Of cases of reflux in infants, most are benign and, in 80% to 95% of cases, resolve by age 1 year,[26] and reflux in older children resolves in a timeframe similar to that of adults. If untreated, GER can result in esophageal strictures, GI hemorrhage, or chronic respiratory disease from the aspiration of GI contents.

Clinical Presentation

In infants, the vomiting and regurgitation of GER occur frequently, and other symptoms often are nonspecific (eg, failure to thrive [FTT], recurrent pneumonia, apnea, dysphagia, reactive airway disease, hematemesis, and anemia).[27,28] A thorough diagnostic workup is generally not necessary in a healthy infant with functional GER presenting as recurrent vomiting. Empiric drug therapy can be initiated after the diagnosis is made based on clinical findings and after other causes of vomiting have been eliminated.[27] Further diagnostic evaluations, however, are indicated for infants and children presenting with additional symptoms of gastroesophageal reflux disease (GERD; eg, FTT, irritability, and respiratory difficulties).[20]

Treatment

Because uncomplicated GER usually resolves spontaneously in infants, therapy should focus on providing symptom relief and maintaining normal growth.[20] Infants and young children with underlying neurologic problems (eg, cerebral palsy) are unlikely to have spontaneous resolutions of GER and frequently require aggressive antireflux therapies and, possibly, surgical intervention.

POSITIONAL AND DIETARY MEASURES

CASE 104-7

QUESTION 1: S.B., a 3-month-old, 13.23-pound (6-kg), breast-fed male infant, has a 2-week history of regurgitation after each feeding. The pediatrician noted that S.B. had not gained weight since his last visit 1 month earlier. The presumptive diagnosis is FTT secondary to GER, and S.B. was referred to a pediatric gastroenterologist.

How should S.B. be treated initially?

S.B. can be treated conservatively because he does not present with life-threatening complications.[27] First, caregiver feedings should be observed to rule out regurgitation caused either by overfeeding or by inappropriate feeding techniques. Sometimes, infants with milk protein allergies can have a similar clinical presentation; therefore, a change to a soy protein formula or hypoallergenic formula should be tried.[27] Interventions to modify an infant's body positioning or to modify infant feedings with milk thickeners are not proved to be effective but are reasonable to undertake.[26] Maintaining S.B. at a 60-degree angle during the day while sitting and at a 30-degree position at night should be implemented in an effort to promote clearance of acid from the esophagus and to minimize reflux after meals. Milk thickeners (most commonly rice cereal in the United States) and more frequent, smaller feedings are also worthwhile interventions, although thickened formula could lead to increased coughing during feeding. Mild cases of GER often can be treated successfully by dietary measures alone, as well as by propping infants in an upright position during, and 1 hour after, feedings.[28] Although the placement of infants in a face-down prone position during sleep can reduce reflux, the greater risk of sudden infant death syndrome (SIDS) in infants younger than age 12 months outweighs the benefits of such positioning.[27] Older children and adolescents should follow the recommended dietary guidelines (ie, avoidance of caffeine, chocolate, and spicy foods) for adults.

DRUG THERAPY

The efficacy of pharmacologic therapy in altering the course of uncomplicated GER in infants has not been proved.[27] In infants or children who present with nonspecific symptoms or complications, such as S.B., acid suppression therapy or prokinetic therapy is warranted even in the absence of documented esophagitis.[27] When esophagitis is present, acid suppression is always recommended to aid in the healing process; however, these agents alone do not rectify the causes of the GER.[27] The various agents to treat infant GER are listed in **Table 104-3**.[27,28]

Table 104-3
Oral Drugs Used to Treat Gastroesophageal Reflux in Infants

Agent	Mode of Action	Oral Dosage
Acid-Suppressing Agents		
Antacids (aluminum or magnesium hydroxide)	Neutralizes acid	0.5–1.0 mL/kg/dose before and after feeding (maximum, 15 mL/dose)
Proton-Pump Inhibitors		
Omeprazole	Decrease acid secretion via inhibition of gastric hydrogen-potassium adenosine triphosphatase.	1–4 mg/kg/day
Esomeprazole		<20 kg: 10 mg/day; >20 kg: 20 mg/day
Lansoprazole		Infants ≥ 3 months: 2 mg/kg/day
Pantoprazole		1–2 mg/kg/day
H_2-Receptor Antagonists		
Cimetidine	Blocks H_2-receptors; ↓ acid secretion	30–40 mg/kg/day divided qid
Famotidine		1 mg/kg/day divided bid
Nizatidine		10–20 mg/kg/day divided bid
Prokinetic Agents		
Metoclopramide	Dopamine antagonist	0.4–0.9 mg/kg/day

Agent	Mode of Action	Oral Dosage
Surface-Active Agents		
Sucralfate	Forms paste and adheres to damaged esophageal mucosa	40–80 mg/kg/day divided qid

bid, two times daily; qid, four times daily.

Acid-suppressant agents

Antacids

Chronic antacid therapy is generally not recommended for the treatment of GER in infants and young children because infants treated with aluminum-containing antacids can accumulate sufficient aluminum to cause osteopenia and neurotoxicity.[27] In addition, information on other antacids in infants is limited; nevertheless, antacids can provide short-term relief of symptoms in older children and adults.

Proton-Pump Inhibitors

Proton-pump inhibitors (PPIs) are superior to histamine-2 receptor antagonists (H_2RAs) in relieving symptoms and in promoting healing of significant esophagitis from GER in infants, young children, and adults.[27–29] PPIs control both basal and meal-stimulated acid secretion, which may in part explain their superior efficacy. Current evaluations of the safety of PPIs in the pediatric population have shown they are not free of adverse effects.[30] Prolonged use of PPIs has been shown to raise concerns for increased risk of infections, vitamin deficiencies, and adverse bone health.[30] In children, increased metabolism and decreased bioavailability necessitate larger milligram per kilogram doses to maintain acid suppression

than in adults; thus, titration of dose to response is necessary, particularly for treatment of esophageal erosions.[29] Omeprazole, lansoprazole, and esomeprazole are available in extended-release capsules, which can be separated, opened, and sprinkled on soft foods. Omeprazole and esomeprazole are also available as granules for an oral suspension. Suspension formulations for both omeprazole and lansoprazole have been extemporaneously compounded and evaluated for stability.

Histamine-2 Receptor Antagonists

H_2RAs reduce histamine-stimulated acid secretion but have limited effects on acid secretion by other chemical mediators and stimuli. In randomized controlled trials, H_2RAs in infants and children relieved symptoms and facilitated the healing of esophageal tissue.[27] Oral liquid formulations are available for most H_2RAs.

Prokinetic agents

Metoclopramide, a dopamine antagonist with cholinergic and serotonergic effects, accelerates gastric emptying, increases lower esophageal sphincter (LES) pressure, enhances esophageal clearance, and accelerates transit time in the small bowel; however, its effects on vomiting and esophageal pH in children with GER has been equivocal.[27] In addition, metoclopramide has been associated with significant CNS (ie, restlessness, drowsiness, and extrapyramidal symptoms) effects, recently receiving a special alert for a higher risk of extrapyramidal symptoms in those age older than 1 year, and rare reports of gynecomastia and galactorrhea.[27] Erythromycin increases GI motility by increasing smooth muscle contractions through its motilin agonistic activity. However, it has been found that there is no sufficient evidence to recommend erythromycin for the treatment of GER in children.[27] The cholinergic agonist, bethanechol, reportedly reduces vomiting episodes in infants with GER[27]; however, its role in treating GER in infants is limited because of its potential to induce bronchospasm and to

stimulate gastric acid secretion. The lack of a suitable commercially available formulation of bethanechol for young infants necessitates its extemporaneous compounding. Baclofen, which decreases transient LES relaxations through its γ-aminobutyric acid agonist actions, could be a future therapeutic option for GER, pending further study.[31] Generally, prokinetic agents are only marginally effective in the management of GER.

Surface-active agents

Sucralfate was equally effective as cimetidine for use in esophagitis[27]; however, its use for GER is more limited because of concern about the adverse effects of aluminum-containing products in infants.

Case 104-7, Question 2: Four weeks after instituting positional and dietary measures, S.B. continues to vomit and still has not been gaining weight. On physical examination, the gastroenterologist notes bilateral wheezes; endoscopy rules out esophagitis. What would be the next step of therapy?

The treatment of S.B. can include acid suppression therapy. Acid suppression therapy in children who have complications from GER can be implemented by a step-up approach in which treatment is initiated with an H_2RA followed by a PPI if no improvement is noted, or through a step-down approach involving a PPI followed by an H_2RA for maintenance therapy. However, initial therapy with a PPI is preferred,[27] and S.B. may be treated with omeprazole 5 mg daily. Granules for suspension may be mixed in 10 mL of water and administered orally.

The effectiveness of acid suppression for managing symptoms of GER in children is not as well documented as it is for healing esophagitis; however, acid suppression is believed to play a useful role in symptom control, particularly for managing respiratory symptoms.[27] Treatment should be continued for at least 3 to 4 months, although the optimal duration of therapy is unknown. If S.B. requires additional drug therapy to control symptoms of GER beyond

age 18 months to 2 years, surgery may be considered because GER is unlikely to resolve spontaneously after this age. Surgery might be considered earlier if S.B. fails medical therapy or if he develops an esophageal stricture, apnea, or recurrent respiratory disease.[27]

COMMON PEDIATRIC INFECTIONS

Acute Otitis Media

Acute otitis media (AOM) is one of the most common infectious diseases seen in childhood.[32] It is most commonly seen in children ages 3 months to 3 years, although the highest incidence occurs between ages 6 and 9 months. Most children will have at least one episode by the time they reach 3 years old.[32] Incidence is higher in the winter months, concurrent with viral upper respiratory illnesses. Several risk factors for AOM have been identified and include age younger than 2 years, early colonization of pathogens and onset of AOM, day care attendance, bottle propping, cleft palate, immune compromise, and Down syndrome.

Eustachian tube dysfunction, either from intermittent causes such as upper respiratory infections or permanent causes such as cleft palate, is the primary condition required for the development of AOM. This results in a defect in the Eustachian tube's ability to equilibrate middle ear pressure. Thus, nasopharyngeal contents, including bacteria, may be aspirated into the middle ear. This process is more likely in infants and young children who have shorter, flatter Eustachian tubes.[33] Changes in pressure can also cause increased vascular permeability, resulting in an effusion. Viral infections contribute by enhancing bacterial transfer from the nasopharynx and adherence to the middle ear because of impairment of the mucociliary apparatus.[33]

S. pneumoniae, nontypeable *Haemophilus influenzae*, and *Moraxella catarrhalis* colonize the nasopharynx early in childhood, and, thus, are the most common pathogens causing AOM.[32,33] The

introduction and widespread use of the pneumococcal conjugate vaccine (PCV13) has changed the landscape of AOM. Specifically, the fraction of *S. pneumoniae* has declined over time, with a rise seen in *H. influenzae*. All three common bacteria possess resistance to β-lactams, thus influencing drug therapy selection.

CASE 104-8

QUESTION 1: C.D. is a 7-month-old, 17.64-pound (8-kg) infant who during the past 36 hours has developed cough, ear pain, and rhinorrhea, became irritable and at times inconsolable, and now has a temperature of 102.4 °F (39.1 °C). Physical examination shows bulging, dark, yellow opaque tympanic membranes bilaterally. This is the first time he has had these symptoms and has had no recent courses of antibiotics.

What signs and symptoms consistent with AOM does C.D. exhibit, and how should AOM be diagnosed?

Very often, as in this patient's case, otitis media is preceded by an upper respiratory tract infection. These viral infections often will produce otitis media with effusion (OME), which typically will cause no more than temporary mild hearing loss. If AOM develops, more signs and symptoms will usually arise. These symptoms can include otalgia (pain causing infants to pull on or rub the ears), fever, irritability, and otorrhea.[34] Unfortunately, aside from otorrhea, these symptoms are nonspecific and may be present in many children who do not have AOM. As a result, a definitive diagnosis may not be easily obtained with symptoms alone. Diagnosis should be confirmed on visualization of the middle ear.

The current AAP guideline on the diagnosis and management of AOM states that a diagnosis of AOM requires mild bulging of the tympanic membrane and either recent onset of ear pain (>48 hours) or intense erythema of the tympanic membrane.[34] Pneumatic otoscopy should be used to confirm the presence of effusion. Middle ear effusion can be differentiated from AOM in that although both present with bulging tympanic membranes, in AOM, the middle ear fluid is more often dark yellow or red.[34] Other diagnostic tools may be used. Tympanometry uses sound waves to measure the

compliance of the tympanic membrane. And in acoustic reflectometry, the absorption of sound waves by the tympanic membrane provides information about the middle ear.[35] C.D.'s fever and irritability along with fluid in the middle ear and bulging, dark yellow tympanic membranes are consistent with the diagnosis of AOM.

Case 104-8, Question 2: How should C.D.'s otitis media be treated?

The AAP recommendations provide for the option to observe without treatment or to treat with antibiotics, depending on the age of the patient and symptoms present.[34] Generally, infants ages 6 months and younger should receive antibiotic therapy in all cases. Infants and children ages 6 months to 2 years can be managed with observation if there is a nonsevere unilateral AOM without otorrhea. Children ages 2 years and older can be managed with observation in bilateral or unilateral nonsevere AOM without otorrhea. Antibiotics are warranted in all cases of AOM with otorrhea or in AOM cases with severe symptoms (eg, temperature >102.2 °F [39 °C] in the past 48 hours).[34]

C.D. appears to have bilateral AOM with severe symptoms based on his fever >102.2 °F (39 °C), so antibiotic therapy is indicated. Despite pneumococcal penicillin resistance rates, initial therapy in most children who have not received amoxicillin in the past 30 days would still be amoxicillin at a dose of 80 to 90 mg/kg/day.[34] Amoxicillin is effective against susceptible and intermediately resistant pneumococcus, it is affordable and palatable, and it has a narrow spectrum of activity. Providers should prescribe amoxicillin/clavulanate in children who have received amoxicillin in the past 30 days, have concurrent purulent conjunctivitis, or have a history of recurrent AOM unresponsive to amoxicillin.[34] Oral cephalosporins, including cefdinir, cefuroxime, or cefpodoxime, are options in patients with an allergy to penicillin.

Whichever treatment course is taken in a patient (observation or antibiotic therapy with amoxicillin or amoxicillin/clavulanate),

effectiveness is assessed for 48 to 72 hours.[34] If the treatment is effective, the patient should defervesce, irritability should decrease, and normal activity should resume (eg, eating and sleeping). If the observation is ineffective, treatment with amoxicillin or amoxicillin/clavulanate is recommended. If amoxicillin or amoxicillin/clavulanate is ineffective for C.D., treatment with an oral cephalosporin (cefdinir or cefpodoxime) or ceftriaxone 400 mg (50 mg/kg) intramuscularly for 1 or 3 days is an option.

The optimal duration of oral antimicrobial agents (eg, amoxicillin, amoxicillin/clavulanate) has been questioned over the past few years. The AAP guideline calls for up to 10 days of oral antibiotic coverage; yet investigators have looked at durations as short as 5 to 7 days.[34,36] The shortened duration strategy has been discussed to have a potential, positive impact on antimicrobial resistance. However, evidence has shown that a shortened course, specifically in children ages 6 to 23 months, resulted in less favorable outcomes and is thus not recommended.[36] In children at least 6 years old with mild-to-moderate symptoms, a 5- to 7-day course may be attempted.[34]

Case 104-8, Question 3: How should C.D.'s otalgia be managed?

Ear pain is a common feature of AOM, and it should be addressed regardless of the decision to use antibiotics or not. Acetaminophen 120 mg (15 mg/kg) or ibuprofen 80 mg (10 mg/kg) can provide adequate relief and are first-line agents in the management of otalgia.[34] Home remedies such as the application of heat or cold may also be helpful.[34] For example, a washcloth can be soaked with very warm water, wrung out, and placed over the ear for comfort for 15 minutes several times per day.

Acute Pharyngitis

Acute pharyngitis is most common in children ages 5 to 15 years and is rare before age 3 years.[37] The etiology is typically viral, but

bacteria such as group A streptococci (GAS, *S. pyogenes*), groups C and G streptococci, *Neisseria gonorrhoeae*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae* may also cause pharyngitis in children.[37] The majority of attention is directed toward the detection and management of GAS infections because, untreated, they may lead to rheumatic fever, a complication progressing to permanent heart disease.

CASE 104-9

QUESTION 1: P.J., a 6-year-old male weighing 51.59 pounds (23.4 kg), presents to the pediatrician's office with fever, sore throat, and headache. His mother reports that he initially reported sore throat about 12 hours ago. His oral temperature this morning was 102 °F (38.89 °C). He takes no medications and has no known drug allergies. Physical examination reveals erythematous tonsils and throat as well as an enlarged anterior cervical lymph node.

Are P.J.'s symptoms more consistent with GAS or viral pharyngitis?

Findings suggestive of GAS tonsillopharyngitis include sudden onset of throat pain, fever, headache, abdominal pain, nausea, vomiting, tonsillopharyngeal edema, enlarged anterior cervical lymph nodes, soft palate petechiae, and a scarlatiniform rash.[37,38] Symptoms that increase the likelihood of a viral cause include rhinorrhea, cough, conjunctivitis, and viral rash.[37,38] P.J. is lacking associated symptoms that would suggest a viral cause and has more symptoms of GAS pharyngitis, but confirmatory testing is needed. In pediatric patients with viral features, judicious use of laboratory testing should occur because children can be carriers of GAS.[39]

DIAGNOSIS

Because clinical and physical findings alone are not definitive for GAS pharyngitis, confirmatory testing is important to determine the need for antibiotic therapy. A rapid antigen detection test is recommended, and, if the result is positive, treatment is initiated. If negative, a throat culture should also be obtained and treatment initiated if the culture grows GAS. However, if one of the newer highly sensitive optical immunoassay or molecular tests is used, a

backup culture may not be necessary.[37] Rheumatic fever can be effectively prevented if treatment is started within 9 days of the start of the illness.[38]

CASE 104-9, QUESTION 2: A rapid antigen detection test for GAS is performed for P.J. and the result is positive. What treatment should be initiated at this time?

TREATMENT

Penicillins remain the agents of choice for GAS pharyngitis.[37] Either oral penicillin, oral amoxicillin, or intramuscular benzathine penicillin may be used. Amoxicillin suspension is more palatable than is penicillin and has the advantage of a once-daily dosing regimen. Intramuscular penicillin is a one-time dose that is helpful in those at risk for nonadherence. In patients with a type I hypersensitivity to penicillins, azithromycin, clarithromycin, or clindamycin may be used. In those with a non–type I allergy to penicillin, a first-generation cephalosporin may be considered. Recommended regimens are summarized in **Table 104-4**.[38] Patients are no longer contagious 24 hours after the first antibiotic dose.[37,38]

Table 104-4
Medication Regimens for the Treatment of Streptococcal Pharyngitis and Prevention of Rheumatic Fever

Medication	Dose	Duration
Amoxicillin	50 mg/kg once a day or 25 mg/kg twice a day (maximum 1 g/day)	10 days
Penicillin VK	Children ≤ 27 kg: 250 mg two or three times a day Children > 27 kg, adolescents: 500 mg two or three times a day or 250 mg four times a day	10 days
Benzathine penicillin G	≤27 kg: 600,000 units IM >27 kg: 1,200,000 units IM	Once
For Patients With Penicillin Allergy		
Cephalexin	20 mg/kg (up to 500 mg) twice a day	10 days
Cefadroxil	30 mg/kg (up to 1 g) once a day	10 days

Medication	Dose	Duration
Clindamycin	7 mg/kg three times a day (maximum 300 mg/dose)	10 days
Azithromycin	12 mg/kg once a day (maximum 500 mg)	5 days
Clarithromycin	7.5 mg/kg twice a day (maximum 250 mg/dose)	10 days

IM, intramuscular.

CORE PRINCIPLES		CHAPTER CASES
RESPIRATORY DISTRESS SYNDROME		
1	Respiratory distress syndrome (RDS) is a major cause of morbidity and mortality in preterm neonates, resulting from pulmonary surfactant deficiency; it is characterized by atelectasis, hypoxemia, decreased lung compliance, small airway epithelial damage, and pulmonary edema.	**Case 105-1 (Question 1)**
2	Beractant, calfactant, and poractant alfa are exogenous surfactants used in the prevention and treatment of RDS in preterm neonates. These agents have been shown to improve oxygenation and lung compliance and decrease the	**Case 105-1 (Question 2–6)**

	need for supplemental oxygen and mechanical ventilation.	
	BRONCHOPULMONARY DYSPLASIA	
1	Bronchopulmonary dysplasia (BPD) is the most common form of chronic pulmonary disease in infants; it is caused by lung immaturity, surfactant deficiency, oxygen toxicity, barotrauma, and inflammation, and is characterized by tachypnea, retractions, and wheezing.	**Case 105-2 (Question 1)**
2	The management of BPD includes supplemental oxygen therapy, mechanical ventilation, and pharmacologic interventions including diuretics, bronchodilators, and corticosteroids. Preventative strategies include caffeine citrate, vitamin A, and azithromycin.	**Case 105-2 (Question 2, 3)**
3	Infants with BPD are at higher risk for experiencing cardiorespiratory problems including pneumonia, pulmonary hypertension, left ventricular hypertrophy, and neurologic and developmental abnormalities.	**Case 105-2 (Question 4, 5)**
	PATENT DUCTUS ARTERIOSUS	
1	Preterm neonates are at high risk for patent ductus arteriosus (PDA), a serious cardiovascular disorder, which may present with tachycardia, wide pulse pressure, bounding pulses, and	**Case 105-3 (Question 1–3)**

	systolic murmur. Complications of PDA include pulmonary edema and heart failure. PDA places the neonate at high risk for BPD, intraventricular hemorrhage, and necrotizing enterocolitis (NEC).	
2	Medical management of PDA includes fluid management, correction of anemia, treatment of hypoxia and acidosis, and pharmacologic therapy with prostaglandin inhibitors (indomethacin, ibuprofen, or acetaminophen) to close the ductus.	**Case 105-3 (Question 4–10)**
NECROTIZING ENTEROCOLITIS		
1	NEC is the most common life-threatening nonrespiratory condition in newborns and is characterized by abdominal distension, bloody stools, metabolic acidosis, and bowel perforation.	**Case 105-4 (Question 1)**
2	The management of NEC includes parenteral nutrition, intravenous antibiotics, and bowel resection. Interventions including trophic feedings, breast milk, probiotics, and a standardized feeding protocol may be used to decrease the incidence of NEC.	**Case 105-4 (Question 2–6)**
NEONATAL SEPSIS AND MENINGITIS		
1	Bacterial sepsis can be classified as early-onset (caused by pathogens colonized from the maternal genital	**Case 105-5 (Question 1)**

	tract) or late-onset sepsis (caused by nosocomial pathogens). Clinical signs can be subtle and nonspecific, especially in preterm neonates.	
2	Selection of empiric intravenous antibiotics is the same for sepsis and meningitis and will depend on nosocomial pathogens commonly isolated in the neonatal intensive care unit, antibiotic resistance patterns, and underlying neonatal risk factors.	**Case 105-5 (Question 2)**
	CONGENITAL INFECTIONS	
1	Congenital infections including herpes simplex virus, syphilis, and cytomegalovirus may result in fetal death, congenital anomalies, serious central nervous system sequelae, intrauterine growth retardation, or preterm birth; if suspected, appropriate diagnostic tests and treatment should be started immediately.	**Case 105-6 (Question 1)**
	APNEA OF PREMATURITY	
1	Pharmacologic treatment of apnea of prematurity includes the use of methylxanthines, specifically caffeine and theophylline, that decrease apneic episodes via both central and peripheral effects.	**Case 105-7 (Question 1)**
2	Caffeine offers several advantages over theophylline for the treatment of apnea, including a wider therapeutic index,	**Case 105-7 (Question 2, 3)**

	fewer adverse effects, prolonged half-life, once-daily dosing, and lack of the need for routine serum drug concentration monitoring.	

NEONATAL SEIZURES		
1	Neonatal seizure activity is a common manifestation of a life-threatening underlying neurologic process. Initial therapy is focused on the treatment of the underlying cause (eg, hypoglycemia, hypocalcemia, infection) and may not include antiepileptic drug therapy.	**Case 105-8 (Question 1–3)**
2	Common antiepileptic medications used to treat neonatal seizure are phenobarbital, phenytoin, levetiracetam, and benzodiazepines.	**Case 105-8 (Question 4, 5)**

INTRODUCTION

The rational use of medications in neonates depends on an appreciation of both the physiologic immaturity and the developmental maturation that influence neonatal drug disposition and pharmacologic effects. Much progress has been made to decrease neonatal mortality and improve the survival of more premature and lower birth weight newborns. Neonates, particularly those of extremely low birth weights (ELBWs), pose a pharmacotherapeutic challenge to the clinician. The alterations of body composition, weight, and size, as well as physiologic and pharmacokinetic parameters, which occur with normal growth and maturation during the first few months of life, are greater than at any other time. Although the amount of neonatal drug information is

increasing, the overall lack of well-designed pharmacokinetic, pharmacodynamic, and pharmacogenomic studies still hinders the clinical use of many drugs in this population. This is especially true for newborns of the lowest birth weights (BWs <0.75 kg). An understanding of common neonatal terminology (**Table 105-1**) is important because every newborn is evaluated and classified at birth according to BW, gestational age (GA), and intrauterine growth status.[1] Pharmacokinetic parameters, pharmacodynamics, and dosing recommendations often are specified according to these terms.[2] Important neonatal pharmacokinetic differences are reviewed in Chapter 102, Pediatric Pharmacotherapy. This chapter focuses on the safe and effective use of medications for common neonatal medical conditions.

Table 105-1
Common Neonatal Terminology

Term	Definition
Gestational age (GA)	*By dates:* The number of weeks from the onset of the mother's last menstrual period until birth
	By examination: Assessment of gestational maturity by physical and neuromuscular examination; GA estimates the time from conception until birth.
Postnatal age (PNA)	Chronologic age after birth
Postmenstrual age (PMA)	GA plus PNA. *Postmenstrual age* (rather than postconceptional age) is the preferred term for use in clinical practice. PMA is considered to be a more accurate term because GA is calculated using the mother's last menstrual period, and the exact date of conception is generally not known.
Postconceptional age (PCA)	Age since conception. This term is not recommended for use in clinical practice and is currently reserved for cases when the exact date of conception is known (ie, assisted reproductive technology). Older literature may use this term to describe the sum of GA plus PNA; thus, it is important to know how this term is defined when used.

Term	Definition
Corrected age (or adjusted age)	PMA in weeks minus 40; represents PNA if neonate had been born at term (40 weeks' GA)
Neonate	A full-term newborn 0–28 days PNA. Some may also apply this term to a preterm neonate who is >28 days PNA, but with a PMA ≤42–46 weeks
Preterm	<37 weeks' GA at birth ▪ Extremely preterm (<28 weeks) ▪ Very preterm (28 0/7–31 6/7 weeks) ▪ Moderately preterm (32 0/7–33 6/7 weeks) ▪ Late preterm (34 0/7–36 6/7 weeks)
Term	37 weeks' 0 days–41 weeks' 6 days (average ~40 weeks') GA at birth ▪ Early term (37 0/7–38 6/7 weeks) ▪ Full term (39 0/7–40 6/7 weeks) ▪ Late term (41 0/7–41 6/7 weeks)
Postterm	≥42 weeks' GA at birth
Extremely low birth weight (ELBW)	Birth weight < 1 kg
Very low-birth weight (VLBW)	Birth weight < 1.5 kg
Low birth weight (LBW)	Birth weight < 2.5 kg
Small for gestational age (SGA)	Birth weight < 10th percentile for GA
Appropriate for gestational age (AGA)	Birth weight between 10th and 90th percentiles for GA
Large for gestational age (LGA)	Birth weight > 90th percentile for GA

RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS) is a major cause of morbidity and mortality in preterm neonates.[3] This clinical syndrome is characterized by respiratory failure with atelectasis, hypoxemia, decreased lung compliance, small airway epithelial damage, and pulmonary edema. The principal cause of RDS is pulmonary surfactant deficiency. Pulmonary surfactant decreases the surface tension at the air–fluid interface in the alveoli and prevents alveolar collapse. Surfactant also facilitates the clearance of pulmonary fluid, prevents pulmonary edema, and stabilizes alveoli during aeration. At birth, the clearance of residual fetal lung fluid is accompanied by an increase in pulmonary blood flow, which facilitates the transition from fetal to adult circulation.[4]

In the fetus, endogenous cortisol stimulates the synthesis and secretion of pulmonary surfactant at 30 to 32 weeks' gestation.[4] However, sufficient amounts of pulmonary surfactant for normal lung function are not present before 34 to 36 weeks' gestation.[4,5] Therefore, the incidence and severity of RDS increase as GA decreases. RDS occurs in ~25% of neonates born at 30 to 31 weeks' gestation, but may occur in as high as 95% to 98% of neonates born at 22 to 24 weeks' gestation.[3]

Without adequate amounts of surfactant, the surface tension within the alveoli is so great that the alveoli collapse (atelectasis), resulting in poor gas exchange (eg, hypoxemia, hypercapnia). Low lung compliance also results, and large inspiratory pressures are needed to aerate the lungs. Unfortunately, the extremely compliant neonatal chest wall makes it difficult to create the large negative inspiratory pressures necessary to open the alveoli. This results in an increased work of breathing and alterations in ventilation and perfusion.[3,4]

Aeration of the surfactant-deficient lung also results in the cyclic collapse and distension of bronchioles, with resultant bronchiolar epithelial injury and necrosis. This epithelial damage causes pulmonary edema by allowing fluid and proteins to leak from the intravascular space into the airspaces and interstitium of the lung. The necrotic epithelial debris and proteins then form fibrous hyaline membranes.[3] Hyaline membranes and pulmonary edema further impair gas exchange.

The inadequate oxygenation and ventilation and increased work of breathing caused by RDS may result in the need for assisted positive-pressure ventilation. Complications of RDS may be related to mechanical ventilation and include pulmonary barotrauma (eg, pneumothorax, pulmonary interstitial emphysema [PIE]), intraventricular hemorrhage (IVH), patent ductus arteriosus (PDA), retinopathy of prematurity (ROP), and chronic lung disease or bronchopulmonary dysplasia (BPD).[3]

Clinical Presentation

CASE 105-1

QUESTION 1: L.D., a 0.68-kg male, was born at 25 weeks' GA via cesarean section as a result of placenta abruption to a 38-year-old gravida 6 para 5 female with gestational diabetes. Apgar scores were 3 at 1 minute, 5 at 5 minutes, and 8 at 10 minutes. Thirty minutes after birth, L.D. appears cyanotic and has retracting respirations with grunting and nasal flaring. His heart rate (HR) is 160 beats/minute, and respiratory rate (RR) is 65 breaths/minute. An arterial blood gas (ABG) on 60% oxygen by noninvasive positive-pressure ventilation (NIPPV) is as follows:

pH, 7.25
P_{CO_2}, 41 mm Hg
P_{O_2}, 71 mm Hg
Base deficit, 8

Based on the blood gas results, L.D. is intubated immediately and placed on positive-pressure–assisted ventilation. An umbilical arterial catheter is inserted for frequent ABG monitoring, and an umbilical vein catheter is inserted for central venous access. L.D.'s chest radiographic shows RDS. Ampicillin 100

mg/kg every 8 hours and gentamicin 5 mg/kg every 48 hours are ordered intravenously (IV) to rule out sepsis.

What is an Apgar score? What risk factors does L.D. have for RDS? What signs and laboratory data are consistent with RDS?

An Apgar score is a method of evaluating the physical condition of a newborn infant immediately after birth. It consists of five clinical signs including HR, respiratory effort, muscle tone, skin color, and reflex irritability. Each sign can receive a score of 0 to 2 points, with a total possible score of 10 points. A score of 7 to 10 is considered normal, whereas scores of 0 to 3 require immediate resuscitation. The Apgar score is routinely done at 1 and 5 minutes of life and is repeated every 5 minutes until a total score of at least 7 is achieved. (For a video of how to assign an Apgar score to newborns, go to https://www.youtube.com/watch?v=cgFRkfpXXH4.) L.D.'s Apgar scores of 3 and 5 at 1 and 5 minutes indicate that he may have experienced some perinatal asphyxia, most likely secondary to maternal placenta abruption. L.D.'s risk factors for RDS are prematurity, male sex, perinatal asphyxia, cesarean section, and maternal gestational diabetes. Other risk factors include second-born twins and maternal–fetal hemorrhage.[3] Clinical signs and laboratory data consistent with RDS in L.D. include tachypnea, cyanosis, retracting respirations, grunting, nasal flaring, hypoxemia, hypercapnia, and a mixed respiratory and metabolic acidosis.[3] Clinical manifestations classically present within the first 6 hours of life.

Tachypnea, the first sign of respiratory distress, is an attempt to compensate for the inadequate ventilation, hypercapnia, and acidosis. L.D.'s retracting respirations (the use of intercostal, subcostal, suprasternal, or sternal accessory muscles) reflect the increased work of breathing necessary to maintain ventilation. His nasal flaring decreases resistance during inspiration and increases oxygenation. Grunting is the result of forceful exhalation against a partially closed glottis in an effort to prolong expiration and maximize oxygenation. Grunting also increases intrathoracic pressure during expiration in an attempt to stabilize the alveoli and prevent

atelectasis. L.D.'s cyanosis, hypoxemia, hypercapnia, and mixed respiratory and metabolic acidosis are consequences of inadequate oxygenation and poor ventilation and are consistent with RDS.[3]

Treatment

Case 105-1, Question 2: What treatments should be initiated for L.D.'s respiratory insufficiency?

Before L.D. is treated for RDS, other causes of respiratory distress must be ruled out. For example, infections (particularly group B streptococcal sepsis or pneumonia) often present with respiratory distress. Because it is difficult to distinguish between RDS and infection, all neonates with severe RDS should receive antibiotics. L.D. was started empirically on antibiotics, and a complete evaluation of possible sepsis should be performed.

Neonates should be treated for RDS as soon as possible and may require ventilatory support. Noninvasive ventilator support such as NIPPV or nasal continuous positive airway pressure (CPAP) has been shown to reduce barotrauma, volutrauma, and airway damage compared to intubation with mechanical ventilation.[3] However, some extremely preterm neonates may require intubation with mechanical ventilation because of persistent symptoms of RDS. Because L.D. failed NIPPV and required intubation, exogenous surfactant should be administered intratracheally as soon as possible. Human surfactant is synthesized and secreted by type II alveolar epithelial cells of the lung. It contains 70% to 80% phospholipids, 10% neutral lipids, and 8% proteins.[5] The major surface-active component is dipalmitoylphosphatidylcholine (DPPC), also known as colfosceril or lecithin. However, this phospholipid slowly adsorbs to the air–fluid interface in the alveoli. Other phospholipids (eg, phosphatidylcholine, phosphatidylglycerol) and four surfactant apoproteins (SP-A, SP-B, SP-C, and SP-D) enhance spreadability and surface adsorption.[5] Adsorption and surface spreading of the surfactant in the alveoli are important determinants of surface tension activity. SP-A and SP-D

both play a role in immune regulation and providing host defense. SP-A may also help regulate alveolar surfactant reuptake and metabolism.[5] SP-B and SP-C are the two most important apoproteins responsible for promoting adsorption and surface spreading of the surfactant in the alveoli to form a phospholipid monolayer.[5] SP-B is thought to be the most critical protein for surfactant activity.

Natural surfactants are derived from bovine or porcine lung lipid or lavage extracts. Modified natural surfactants are lung lipid extracts supplemented with phospholipids or other components.[3] Currently, three surfactant products are commercially available for clinical use in the United States: beractant (Survanta®), calfactant (Infasurf®), and poractant alfa (Curosurf®). Beractant and calfactant are U.S. Food and Drug Administration (FDA) approved for the prevention (ie, prophylaxis) and treatment (ie, rescue therapy) of RDS, whereas poractant alfa is only approved for treatment. Animal-derived products contain variable amounts of SP-B and SP-C, lipids, and phospholipids. Lucinactant (Surfaxin®), a synthetic surfactant that contains phospholipids and high concentrations of sinapultide (KL4), a synthetic peptide that mimics human SP-B, was approved in 2012 but was removed from the market in 2015. See **Table 105-2** for comparisons.[6–8]

Table 105-2
Comparison of Currently Marketed Surfactant Products

Variable	Beractant (Survanta®)	Calfactant (Infasurf®)	Poractant Alpha (Curosurf®)
Type and source	Modified natural surfactant, bovine lung mince extract	Natural surfactant, calf lung wash	Natural surfactant, porcine lung mince extract
PL	Natural and supplemented DPPC with mixed PL	Natural DPPC with mixed PL	Natural DPPC with mixed PL
Proteins	SP-B and SP-C	SP-B and SP-C	SP-B and SP-C
Indications	Prophylaxis and rescue therapy	Prophylaxis and rescue therapy	Rescue therapy
Criteria for prophylaxis	Birth weight <1.25 kg or evidence of surfactant deficiency	Premature neonates <29 weeks' GA at high risk for RDS	Not approved
Recommended dose	4 mL/kg (100 mg/kg PL)	3 mL/kg (105 mg/kg PL)	*Initial dose:* 2.5 mL/kg (200 mg/kg PL); *Repeat dose:* 1.25 mL/kg (100 mg/kg PL)
Recommended regimen for prophylaxis	Give first dose ASAP after birth, preferably within 15 minutes; repeat as early as 6 hours up to a total of four doses if infant remains intubated and requires FIO_2 ≥0.3 with PaO_2 ≤80 mm Hg.	Give first dose ASAP after birth, preferably within 30 minutes; repeat every 12 hours up to a total of three doses if infant remains intubated.	Not approved
Criterion for rescue therapy	Infants with confirmed RDS who require endotracheal intubation	Infants ≤72 hours of age with confirmed RDS who require endotracheal intubation	Infants with confirmed RDS who require endotracheal intubation
Recommended regimen for rescue therapy	Give first dose ASAP after RDS diagnosed, preferably by 8 hours postnatal age; repeat as early as 6 hours up to a total of four doses if infant remains intubated and requires FIO_2 ≥0.3 with PaO_2 ≤80 mm Hg.	Give first dose ASAP after RDS diagnosed; repeat every 12 hours up to a total of three doses if infant still remains intubated.	Give first dose ASAP after RDS diagnosed; repeat every 12 hours up to a total of three doses if infant remains intubated.
Recommended administration technique	Administer through side port of ETT adapter via ventilator *or* through disconnected ETT via 5F catheter, divide dose into four aliquots with position change.	Administer through side port of ETT adapter via ventilator *or* through disconnected ETT via 5F catheter, divide dose into two aliquots with position change.	Administer through side port of ETT adapter via ventilator *or* through disconnected ETT via 5F catheter, divide dose into two aliquots with position change.
Special instructions	Warm to room temperature before use; do not shake.	Gentle swirling of the vial may be necessary for redispersion; warming to room temperature is not necessary; do not shake.	Warm to room temperature before use; do not shake.
Stability	If warmed to room temperature for <24 hours, unopened, unused vials may be returned only once to refrigerator; single-use vial contains no preservative, discard unused portion.	If warmed to room temperature for <24 hours, unopened, unused vials may be returned once to refrigerator; single-use vial contains no preservative, discard unused portion.	If warmed to room temperature for <24 hours, unopened, unused vials may be returned only once to refrigerator; single-use vial contains no preservative, discard unused portion.
Cost per vial	$459.60 (4 mL), $813.46 (8 mL)[a]	$514.50 (3 mL), $910.64 (6 mL)[a]	$548.76 (1.5 mL), $1082.09 (3 mL)[a]

ASAP, as soon as possible; DPPC, dipalmitoylphosphatidylcholine; ETT, endotracheal tube; F, French; FIO_2, fractional inspired oxygen; PaO_2, partial pressure of oxygen; PL, phospholipids; RDS, respiratory distress syndrome.

CASE 105-1, QUESTION 3: What are the effects of an exogenously administered surfactant that can be expected in L.D.?

Oxygenation and lung compliance rapidly and markedly improve after the administration of the surfactant. It should be expected that supplemental oxygen and mechanical ventilation may need to be significantly reduced. The increased lung compliance and decreased need for high inspiratory pressures result in a dramatic decrease in the incidence of pneumothorax and PIE. Survival in treated infants increases by ~40% regardless of BW or GA, and neonatal mortality from RDS is decreased to ~20%.[9] Other complications of RDS such as severe BPD, IVH, NEC, ROP, and PDA have not been decreased consistently with surfactant therapy.[10]

CASE 105-1, QUESTION 4: Which surfactant is appropriate and when should it be administered to L.D.?

PRODUCT SELECTION

Previous trials comparing natural surfactant products (poractant vs beractant, calfactant vs beractant, poractant alfa vs calfactant) have demonstrated that poractant and calfactant result in a significantly faster weaning of supplemental oxygen and mean airway pressure compared to beractant. Furthermore, a lower mortality rate at 36 weeks' postmenstrual age (PMA) was seen with a higher initial dose of poractant 200 mg/kg; however, there were no differences seen with the duration of mechanical ventilation and supplemental oxygen, the incidence of BPD, and other secondary outcomes.[11] To date, there is only one trial comparing the three natural surfactant products for the treatment of RDS. Overall, there were no significant differences in the incidence of pneumothorax, PIE, death, and the combined variable of BPD or death among the three surfactant products.[12] Long-term neurodevelopmental outcomes assessed at 18 to 24 months of corrected age of infants receiving beractant versus poractant for RDS found no significant difference between products.[13]

Previous studies reported significant cost savings associated with poractant (owing to fewer required additional doses) compared with beractant.[11] However, when comparing the average medication cost

per patient, poractant was significantly higher compared to beractant.[14] This may be due to more vials required to administer each treatment dose because poractant comes in smaller vial sizes (1.5 mL, 3 mL) compared to beractant (4 mL, 8 mL). In addition, costs associated with reintubation in preterm infants were similar between beractant and poractant.[15] A recent study using a large health care database reported similar adjusted length of stay (LOS) and costs between the three surfactants. However, infants treated with beractant or poractant had significantly lower rates of mortality compared to calfactant. Furthermore, infants treated with poractant were less likely to receive mechanical ventilation at days 3 and 7 compared to beractant and calfactant.[16]

Based on these comparative trials, it appears that poractant, given at a dose of 200 mg/kg, may be the favorable surfactant therapy because it resulted in a faster weaning of oxygen and mean airway pressure and a decrease in mechanical ventilation and mortality. However, long-term outcomes (eg, BPD and other secondary outcomes) are similar between the three surfactant products.

TIME AND METHOD OF ADMINISTRATION

Historically, surfactant therapy can be administered as prophylaxis, with the first dose given before the newborn's first breath or before positive-pressure ventilation, usually in the delivery room.[9] However, owing to the increased use of antenatal steroids, prophylactic surfactant administration is no longer indicated in infants at risk for RDS. Surfactant can be administered as *early* rescue (defined as the administration of surfactant within the first 2 hours of life) or *late* rescue (defined as treatment after >2 hours of life). When comparing *early* versus *late* rescue therapy (regardless of routine initial use of CPAP), infants treated in the *early* group had significant decreases in the incidence of mortality, air leak, BPD, and the combined variable of BPD or death.[10] Thus, CPAP should be utilized initially, with selective early rescue surfactant administration in infants in whom symptoms of RDS persist.

Surfactant should be administered by qualified physicians in the presence of nursing and respiratory therapy personnel. (For a video on surfactant administration, go to https://www.youtube.com/watch?v=SKcJpZTHKo8.) Surfactants can be administered through a side port of endotracheal tube (ETT) adapter via ventilator or through a disconnected ETT via a 5F catheter (see Table 105-2). Both administrative techniques are effective and are not significantly different with regard to clinical outcomes.[10] Several alternative methods of surfactant administration have been utilized in an effort to avoid mechanical ventilation. The "INSURE" (*IN*tubate–*SUR*factant–*E*xtubate) technique is a strategy that administers surfactant during a brief intubation followed by immediate extubation to nasal CPAP. This technique was associated with a reduced need for mechanical ventilation and subsequent BPD.[10] Recently, a less invasive surfactant administration (LISA) has been shown to be an effective delivery method for surfactant administration for the treatment of RDS.[17,18] LISA consists of surfactant instillation through a cannula into the trachea while the infant continues to breathe spontaneously on CPAP. Recent studies have reported significant decreases in the need for mechanical ventilation, BPD, and a composite outcome of death or BPD associated with a LISA.[17,18] Long-term follow-up at 24 months' PMA reported no significant differences in neurodevelopmental and respiratory outcomes between INSURE and LISA.[19] Although LISA appears promising, owing to limited data, intratracheal administration of surfactant combined with INSURE remains the administration of choice for surfactants.

Because surfactant works better if given earlier in the course of RDS, it is important to determine who is at the highest risk for RDS. Unfortunately, the exact criteria to clinically determine high-risk newborns are still unclear. Surfactant treatment should be administered as soon as clinical signs of RDS appear. The administration of CPAP after birth with subsequent selective surfactant therapy should be the preferred method. Early therapy avoids progression of the disease and the potential for decreased surfactant effectiveness; therefore, it should be considered in

preterm infants born at <30 weeks' gestation who need mechanical ventilation because of severe RDS. Because L.D. has clinical, laboratory, and radiographic findings consistent with RDS, a dose of 2.5 mL/kg (200 mg/kg phospholipid) of poractant should be administered to L.D. intratracheally immediately within 1 hour of age with subsequent extubation to CPAP as soon as possible.

CASE 105-1, QUESTION 5: Within 1 hour of poractant administration, L.D.'s oxygenation improved, and the fraction of inspired oxygen (FIO_2) was weaned from 60% to 40%. Ten hours later, the ABGs revealed the following:

pH, 7.30
PCO_2, 45 mm Hg
PO_2, 50 mm Hg
Base , Deficit2
O_2 saturation, 90% on the following ventilator settings: FIO_2, 0.40; intermittent mechanical ventilation (IMV), 30; PIP, 18; positive end-expiratory pressure (PEEP), +5

Should another dose of poractant be administered?

The response to a single dose of surfactant usually is transient; thus, more than one dose may be needed. Response to surfactant therapy can be variable, especially in preterm newborns or in those who require high oxygen and ventilatory pressures.[3] Reasons for lack of response include surfactant inhibition by proteins that have leaked into the alveolar spaces, inactivation of surfactant by inflammatory mediators (free oxygen radicals, proteases), presence of conditions that can decrease surfactant effectiveness (eg, pulmonary edema), or poor delivery of surfactant to the alveoli (owing to atelectasis).[3] The degree of responsiveness to surfactant also decreases with increasing postnatal age (PNA).[9]

Although the indications for subsequent doses of surfactant vary, persistence of respiratory failure is the major clinical indicator for retreatment. In practice, most infants require only one dose of surfactant. This may be related to advances in neonatal and perinatal management and an increased use of antenatal steroids. However, there are neonates who may be more likely to require

more than one dose; these include those who were not exposed to antenatal steroids and/or those with extreme prematurity (<26 weeks' gestation). A second dose of poractant should be given to L.D. because he still requires mechanical ventilation with relatively high inspiratory pressures and supplemental oxygen (F_{IO_2} ≥0.4) to maintain an arterial P_{O_2} of at least 50 mm Hg and oxygen saturation of 90%.

Case 105-1, Question 6: On rounds, the medical resident asks you about the complications of surfactant treatment in premature infants. What information on adverse effects and their frequency would you provide for the medical team?

The most common adverse effects of surfactant therapy are related to the method of administration.[6–8,10] During administration, L.D. may experience bradycardia and oxygen desaturation secondary to vagal stimulation and airway obstruction.[6–8] These adverse events might require temporary discontinuation of surfactant administration and increased ventilator support.

The risk of pulmonary hemorrhage, which usually occurs within the first 72 hours of life, can be found in up to 6% of neonates receiving surfactant therapy.[3] However, pulmonary hemorrhage has not been consistently reported in recent studies; thus, the association between surfactant therapy and this disorder is questionable.[3] Furthermore, the benefits of surfactant therapy far outweigh the potential risk of pulmonary hemorrhage.

BRONCHOPULMONARY DYSPLASIA

CASE 105-2

Question 1: J.T. is a 4-week-old, 1.2-kg female who was born at 25 weeks' gestation. Her medical history includes RDS, episodes of sepsis and pneumonia, and 3 weeks of parenteral nutrition. J.T. has also failed extubation

numerous times and is currently requiring mechanical ventilation with an F_{IO_2} of 50%. Current vital signs are as follows:

RR, 60 breaths/minute
HR, 150 beats/minute
Blood pressure (BP), 80/55 mm Hg
O_2 saturation, 90%

On physical examination, J.T. has intercostal and subcostal retractions, shallow breathing, and an expiratory wheeze. Bilateral diffuse haziness with lung hyperinflation, focal emphysema, atelectasis, and irregular fibrous streaks are seen on chest radiograph. J.T. is currently receiving enteral feedings with a preterm 20-cal/oz formula at 40 mL every 3 hours. Based on these findings, the diagnosis of BPD is made.

What is the pathogenesis of BPD? What risk factors for BPD does J.T. have? What clinical signs and laboratory evidence of BPD are apparent in J.T.?

BPD (also known as chronic lung disease) is the most common form of chronic pulmonary disease in infants. The disease develops in newborns who require supplemental oxygen and positive-pressure ventilation for RDS or other primary lung disorders. BPD is a significant cause of infant morbidity and mortality. BPD affects 10,000 to 15,000 infants in the United States each year.[20] The incidence and severity of BPD are inversely related to GA and BW (80% of infants born at 22–24 weeks' GA compared to 20% born at 28 weeks' GA).[21] Despite advances in clinical practice, the incidence of BPD from 2005 to 2014 has not decreased; this may be due to an increased survival of extremely preterm infants and/or how BPD is defined.[20]

Historically, BPD was defined as those who require oxygenation therapy at 28 days of life, which was subsequently changed to the need for oxygen at 36 weeks' PMA.[20] In 2001, a severity-based definition of BPD, categorized as mild, moderate, or severe, based on oxygen or respiratory support requirement at 36 weeks' PMA was developed by the National Institute of Child Health and Human Development (NICHD).[22] Owing to the increasing survival of extremely preterm infants and the new respiratory support strategies such as NIPPV, diagnosing BPD accurately remains a challenge. In addition, the current definition does not account for infants who die

from severe respiratory failure before 36 weeks' PMA. This has led to a revised definition of BPD, developed by an NICHD workshop panel. The revised definition removed the criteria for an oxygen requirement of 28 days before 36 weeks' PMA, added a requirement for radiographic confirmation of parenchymal lung disease, and used a severity grading of I to III that incorporates newer modes of noninvasive ventilation and includes infants dying from respiratory failure before 36 weeks' PMA.[20] They proposed using a severity grading system rather than mild, moderate, or severe because the latter may be more subjective, which can result in various interpretations. **Table 105-3** outlines the two definitions proposed by the NICHD.[20,22]

Table 105-3
Definition of Bronchopulmonary Dysplasia: Based on Severity

NICHD 2001			NICHD 2018				
GA	<32 weeks	>32 weeks	**GA**	<32 weeks			
Time of Assessment	36 weeks' PMA or DC, whichever comes first	>28 days but <56 days' PNA or DC, whichever comes first	**Criteria**	BPD and ■ Persistent parenchymal lung disease confirmed on radiograph *and* ■ Require one of the following O_2 therapy ≥3 days to maintain O_2 saturation 90%–95% at 36 weeks' PMA			
Criteria	Treatment with O_2 >21% for at least 28 days *and*			**Invasive IPPV[a]**	**NCPAP NIPPV, or NC ≥3 L/minute**	**NC 1–2.9 L/minute or hood O_2**	**NC < 1 L/minute**
Mild BPD	RA at 36 weeks' PMA or DC, whichever comes first	RA by 56 days' PNA or DC, whichever comes first	**Grade I**	—	21%	22%–29%	22%–70%
Moderate BPD	Require <30% O_2 at 36 weeks' PMA or DC, whichever comes first	Require <30% O_2 at 56 days' PNA or DC, whichever comes first	**Grade II**	21%	22%–29%	≥30%	>70%
Severe BPD	Require ≥30% O_2 and/or positive pressure (PPV or NCPAP) at 36 weeks' PMA or DC, whichever comes first	Require ≥30% O_2 and/or positive pressure (PPV or NCPAP) at 56 days' PNA or DC, whichever comes first	**Grade III**	>21%	≥30%	—	—
			Grade IIIA	Early death occurring 14 days' PNA to 36 weeks' PMA because of persistent parenchymal lung disease and respiratory failure not attributable to other neonatal comorbidities			

DC, discharge; GA, gestational age; IPPV, intermittent positive-pressure ventilation; NC, nasal cannula; NCPAP, nasal continuous positive airway pressure; NICHD, National Institute of Child Health and Human Development; NIPPV, noninvasive positive-pressure ventilation; O_2, oxygen; PMA, postmenstrual age; PNA, postnatal age; PPV, positive-pressure ventilation.

[a]Does not include infants ventilated for primary airway disease or central respiratory control condition.

Pathogenesis and Clinical Manifestations

The cause of BPD seems to be multifactorial. Lung immaturity, surfactant deficiency, oxygen toxicity, barotrauma or volutrauma, and inflammation all play important roles. Premature infants, especially those at <24 weeks' gestation, are at a higher risk for BPD owing to lung immaturity.[21] Surfactant deficiency and the immature parenchymal structure of the lung and chest wall contribute to the development of BPD. Oxygen therapy, which causes a release of free oxygen radicals, is directly associated with the pathogenesis of BPD. Prolonged exposure to high oxygen concentrations and free oxygen radicals causes tissue damage, alveolar–capillary leaks, and atelectasis with resultant impaired gas exchange and pulmonary edema.[23] This may lead to the chronic pulmonary fibrotic changes seen in infants with BPD. In term infants, the lungs contain antioxidant enzymes that help protect the lungs from damage produced by free oxygen radicals. However, in preterm infants, the concentration of antioxidant enzymes may be low or absent. Therefore, premature infants are more susceptible to develop BPD than are term infants.

Barotrauma secondary to positive-pressure ventilation is also a major factor in the pathogenesis of BPD, independent of oxygen toxicity.[23] Barotrauma is caused by repetitive distension of the terminal airways during mechanical ventilation. This results in disruption of the epithelium and an increase in capillary permeability to proteinaceous fluid. The severity of lung injury is related to the amount of positive peak pressure used. Volutrauma is also involved in the pathogenesis of BPD and is caused by high tidal volume

ventilation and overdistension. The combined iatrogenic insults of oxygen toxicity and barotrauma or volutrauma, both inflicted on an immature lung for an extended time, can worsen lung damage.

The presence of a PDA may also increase the risk of BPD due to increased pulmonary blood flow resulting in increased interstitial fluid, decreased pulmonary compliance, and increased airway resistance. This can lead to prolonged mechanical ventilation with higher pressures and oxygen concentration.[21,23] However, clinical studies evaluating early PDA closure did not report a decrease in the incidence of BPD.[23]

Infection and nutrient deficiency may also play a role in the pathogenesis of BPD. The presence of chorioamnionitis may increase the infants' risk factor for BPD, although recent studies failed to report similar findings.[21] Pathogens such as *Ureaplasma, Chlamydia,* or cytomegalovirus may cause chronic infection and contribute to the development of BPD.[23] Colonization with ureaplasma may cause increased inflammation, fibrosis, and impaired airway development. Several meta-analyses have shown direct correlations between *Ureaplasma* respiratory tract colonization and the development of BPD in preterm infants.[23] Deficiencies in nutrients such as vitamin A (retinol) or trace elements such as zinc, copper, and selenium (which are integral components of the antioxidant enzyme structure) may also play a role in the pathogenesis of BPD.

J.T. has two of the most important risk factors for BPD, low BW and decreased GA. She is also at risk for BPD owing to mechanical ventilation, oxygen toxicity, and fluid excess (160 mL/kg/day). Other risk factors not pertaining to J.T. include male sex, White ethnicity, and persistent PDA.[21]

BPD is characterized by tachypnea with shallow breathing, intercostal and subcostal retractions, and expiratory wheezing as demonstrated in J.T. Other signs and symptoms include rales, rhonchi, cough, airflow obstruction, airway hyperreactivity, increased mucus production, hypoxemia, and hypercarbia.[23] J.T.'s chest radiograph shows evidence of BPD, including focal emphysema, atelectasis, bilateral diffuse haziness (interstitial thickening) with

increased expansion of the lungs, and irregular fibrous streaks. Mucous plugging, sepsis, and pneumonia can also develop in infants with BPD on chronic mechanical ventilation. Infants with severe BPD eventually experience cardiovascular complications such as pulmonary hypertension, cor pulmonale, systemic hypertension, and left ventricular hypertrophy. In addition to chronic respiratory and cardiovascular complications, infants with BPD have significant growth, nutritional, and neurodevelopmental problems.[23]

Management

Case 105-2, Question 2: What nonpharmacologic and therapeutic agents should be used to manage BPD in J.T.?

The medical management of infants with BPD includes supplemental oxygen therapy, mechanical ventilation, fluid restriction, nutritional management, and various pharmacologic interventions. Supplemental oxygen administered via mechanical ventilation, NIPPV, CPAP, or nasal cannula should be provided to maintain an oxygen saturation of 90% to 95% and prevent hypoxemia.[23] Because infants with BPD often accumulate excessive interstitial fluid in the lung, fluids should be restricted to 120 to 130 mL/kg/day to prevent congestive heart disease and pulmonary edema. Because infants with BPD have a 25% increase in caloric expenditure, high-calorie formulas (eg, 24 or 27 kCal/oz) may be used to optimize calories while restricting fluid intake.[23] If this increased energy is not provided, infants are at risk for undergoing a catabolic state that places them at higher risk for experiencing more severe BPD (inadequate nutrition may potentiate the toxic effects of oxygen toxicity and barotrauma). Malnutrition may impair growth and delay the development of new alveoli. In addition, malnourished infants are at higher risk for infection and oxygen toxicity.[23] The goal of nutritional therapy is to produce weight gains of 10 to 30 g/day, which can usually be accomplished by providing 140 to 160 kCal/kg/day.[23] If infants do not tolerate enteral feedings, parenteral

nutrition should be substituted until the gastrointestinal (GI) tract becomes more functional. Because J.T. is on a 20-cal/oz formula, switching her to a high-calorie formula would help optimize her weight gain. Her fluids should be restricted to 120 to 130 mL/kg/day.

PHARMACOLOGIC THERAPY

The treatment of BPD consists of multiple-drug therapy, which includes diuretics, bronchodilators, and corticosteroids.[2,20,21,23–30] Despite the advancement of drug therapy, none of these drugs has been shown to reverse pulmonary damage in infants with BPD. Instead, they are used primarily to reduce clinical symptoms and to improve lung function.

Diuretics

Infants with BPD are particularly prone to pulmonary edema from cardiogenic and noncardiogenic factors. Left ventricular failure may worsen the already existing right ventricular failure. Pulmonary vascular permeability is increased because of the disruption of the alveolar–capillary unit and causes an increased amount of fluid in the interstitium. Diuretics help reduce interstitial lung water, lower pulmonary vascular resistance, and improve gas exchange, thereby reducing oxygen requirements.[21,24] The most commonly used diuretics are furosemide, thiazides, and spironolactone. Furosemide is the drug of choice because of its potent diuretic effect. In addition, it increases lymphatic flow and plasma oncotic pressure and decreases pulmonary interstitial edema. The use of furosemide in infants with BPD was associated with short-term improvement in lung compliance and oxygenation, decreased total pulmonary resistance, and facilitation in ventilator weaning.[21,24] Although diuretics are commonly used in the management of BPD, especially in extremely preterm infants, it does not effectively treat established BPD.[21,24] In addition, long-term benefits such as reductions in mortality, hospitalization, or duration of positive-pressure ventilation have not been reported. Tolerance to furosemide may develop after a few days of therapy; this may be a result of the contraction in

extracellular volume, which can lead to a compensatory increase in water and sodium reabsorption in the renal tubules. Hypochloremic metabolic alkalosis, hypokalemia, and hyponatremia are the common short-term adverse effects of furosemide. Other adverse effects include volume depletion, hypercalciuria, nephrocalcinosis, osteopenia, and ototoxicity.[2,21,24] Long-term adverse effects of furosemide on bone mineralization and growth are unknown.

Thiazide diuretics (eg, hydrochlorothiazide) in combination with a potassium-sparing diuretic (eg, spironolactone) can improve lung function and decrease oxygen requirements with increased diuresis.[24] Although less potent than is furosemide, the combination of these two diuretics can reduce the incidence of hypokalemia commonly associated with loop or thiazide diuretics. Adverse effects commonly seen with this combination include hyponatremia, hyperkalemia or hypokalemia, hypercalciuria, hyperuricemia, hyperglycemia, azotemia, and hypomagnesemia.[2] In summary, despite insufficient evidence of long-term efficacy (eg, decreased oxygen requirement, need for mechanical ventilation, death, severity of BPD) and the potential for adverse effects, diuretics are often used in the management of BPD to provide short-term improvement in pulmonary edema and reduce the need for ventilatory support. Future studies are needed to identify which infants with BPD will most likely benefit from diuretic therapy such as those with left ventricular dysfunction or pulmonary hypertension.[24] Because J.T. has evolving BPD and has not been able to be weaned off the ventilator, furosemide 2 mg/kg given every 12 hours enterally may be considered. J.T. should be monitored and treated for electrolyte disturbances while on furosemide.

Case 105-2, Question 3: One week after starting furosemide, J.T. still requires high ventilatory settings and is unable to be weaned from the ventilator. What other therapeutic agents may be considered to treat J.T.'s BPD?

Inhaled bronchodilators

Infants in the early stages of BPD generally have airway hyperactivity and smooth muscle hypertrophy. They are also at higher risk for bronchoconstriction owing to increased airway resistance secondary to hypoxia. Therefore, the use of bronchodilators may be helpful in these infants. β_2-Agonists such as albuterol have been shown to provide short-term improvements (4 hours) in lung compliance and pulmonary resistance owing to bronchial smooth muscle relaxation; however, they are not effective in all infants with BPD.[21,23,24] A recent survey reported variations in prescribing inhaled bronchodilators in infants with BPD, which raises a question on their efficacy.[24] Data from an administrative database reported that prolonged mechanical ventilation was the best predictor of inhaled bronchodilator usage in infants with evolving BPD.[25] In addition, tachycardia and hypertension are commonly seen, and tolerance may develop with prolonged administration. Therefore, inhaled bronchodilators should be reserved for infants with an acute exacerbation of airway obstruction and who have clearly demonstrated improvements during therapy. There are no well-designed studies evaluating the chronic use or long-term outcome of using inhaled bronchodilators in infants with BPD. Despite the lack of meaningful long-term clinical outcomes associated with β_2-agonists and the variable results, their use continues to be very common in preterm infants with BPD. Further studies evaluating the efficacy and safety of long-term inhaled bronchodilator therapy and to identify those who will most likely benefit from treatment are needed.

Inhaled anticholinergics (eg, ipratropium bromide) have produced short-term benefits (~4 hours) in infants with BPD by improving pulmonary function.[24] Inhaled anticholinergics, which relax bronchial smooth muscle and decrease mucus secretion, are generally reserved for infants who are intolerant to albuterol or as an adjunct to albuterol if clinical improvement is not seen.[24] The combined therapy of albuterol and ipratropium may be more effective than either drug alone.[24] The adverse effect profile of ipratropium is minimal because the drug is poorly absorbed.

A major problem with inhaled bronchodilators is their method of administration and drug delivery. Inhaled bronchodilators can be given by jet or ultrasonic nebulization or via a metered-dose inhaler (MDI).[25] For ventilator-dependent infants receiving MDIs, the MDI is connected to an adapter that is attached to the ventilator circuit and ETT. MDIs can also be given through bag ventilation via the ETT. For nonventilated infants, the MDI can be given using a valved holding chamber device and a face mask.

Compared with MDIs, nebulization has several disadvantages including the loss or inefficient delivery of drug and cooling of the inspired oxygen mixture. In several neonatal studies, MDIs with a spacer provided more efficient delivery of inhaled bronchodilators and greater improvements in oxygenation and ventilation; smaller doses and a shorter treatment time were also used.[25] Furthermore, when comparing the three different devices, the MDIs with a spacer and the ultrasonic nebulizer are more efficient in delivering aerosols to neonates than is the jet nebulizer.[25] In addition, MDIs are less expensive than is nebulization. Therefore, the use of MDIs with an appropriate spacing device is preferred for most infants.

Corticosteroids

Corticosteroids, particularly dexamethasone, have been used extensively for the prevention and treatment of BPD. Mechanisms of action of corticosteroids include (a) reduction of polymorphonuclear leukocyte migration to the lung; (b) reduction of lung inflammation; (c) inhibition of prostaglandin, leukotriene, tumor necrosis factor, and interleukin synthesis; (d) reduction of elastase production; (e) stimulation of surfactant synthesis; (f) reduction of vascular permeability and pulmonary edema; (g) enhancement of β-adrenergic receptor activity; (h) reduction of pulmonary fibronectin (which can reduce the risk of interstitial fibrosis); and (i) stimulation of serum retinol concentrations.[2,23,26]

Systemic Corticosteroids

Systemic corticosteroids are associated with many serious short-term adverse effects, including hyperglycemia, increased BP, hypertrophic cardiomyopathy, GI bleeding, intestinal perforation, pituitary–adrenal suppression, bone demineralization, poor weight gain, and increased risk of infection.[2,23] Serious long-term adverse effects such as cerebral palsy (CP) and neurosensory disability have also been identified in preterm infants who receive systemic corticosteroids.[23,26]

Early (Age Younger Than 8 Days) Systemic Corticosteroids

Early use of dexamethasone was associated with significant decreases in the incidences of BPD and the combined outcome of death or BPD at 28 days' PNA and at 36 weeks' PMA, PDA, severe ROP, and the need for late corticosteroid treatment.[26] However, its use was associated with significant increases in the incidence of CP, and combined death or CP. In contrast to dexamethasone, early hydrocortisone use was not associated with significant decreases in the incidences of BPD, death, or combined death or BPD at 36 weeks' PMA. However, its use was not associated with an increased risk of CP or the combined outcome of death or CP.[26,27] Both drugs significantly increase the risk of GI perforation, whereas dexamethasone also increases the risk of hyperglycemia and hypertension.[26] The authors concluded that despite the short-term benefits of dexamethasone and the lack of long-term adverse effects of hydrocortisone, early use of both dexamethasone and hydrocortisone is not recommended.[27,28]

Late (Age Older Than 7 Days) Systemic Corticosteroids

As with early use, late dexamethasone administration was associated with significant decreases in the incidences of BPD and the combined outcome of death or BPD at 28 days' PNA and at 36 weeks' PMA, and the need for late corticosteroid treatment and home oxygen.[26] However, the incidence of severe ROP (not blindness), cardiomyopathy, hyperglycemia, and hypertension was significantly higher in the infants treated with dexamethasone.

Contrastingly, the late use of hydrocortisone was not found to be associated with significant decreases in the incidence of BPD, death, and the combined death or BPD at 36 weeks' PMA.[27] Interestingly, both drugs, when administered after 7 days of life, did not significantly increase the rate of CP or combined death or CP.[26,27] There is currently one trial under way, conducted by the NICHD, evaluating late use of hydrocortisone on BPD at 36 weeks' PMA, mortality, and survival free of moderate-to-severe disability at 22 to 26 weeks' corrected age.[26]

In 2010, the American Academy of Pediatrics (AAP) issued a policy statement that low (<0.2 mg/kg/day) and high dexamethasone dosing regimens (≥0.5 mg/kg/day) as well as high-dose hydrocortisone (3–6 mg/kg/day) are not recommended owing to the insufficient evidence and absence of improved short- and long-term outcomes from randomized trials.[28] Early low-dose hydrocortisone (1 mg/kg/day) given within the first 2 weeks of life may benefit a specific patient population.[28] Clinicians must weigh the potential risks of BPD with the potential adverse effects associated with glucocorticoids; therapy should be considered in very low-birth weight (VLBW) infants at high risk for experiencing BPD (eg, those still on mechanical ventilation after age 1–2 weeks). Parents should be fully informed about the short- and long-term adverse effects of systemic corticosteroids.[28] Despite the AAP recommendation, some clinicians would still consider administering a short course of low-dose systemic corticosteroid in infants at high risk for BPD to help facilitate extubation.

Based on current evidence, it appears that late use of dexamethasone may be of benefit to infants at highest risk for severe BPD. The NICHD National Research Network developed an online risk calculator (https://neonatal.rti.org/index.cfm) that can be used to predict infants born at 23 to 30 weeks' GA up to 28 days' PNA at high risk for BPD.[21] A meta-regression analysis demonstrated that the impact of postnatal steroids on the combined outcome of death or CP was modified by the risk of BPD.[23,26] When postnatal dexamethasone was used in infants with a low-risk factor for BPD (<35%), there was a significant increase in the risk of death

or CP. However, when used in infants with a higher risk factor for BPD (>65%), a significant reduction in the risk of death or CP was found. Overall, infants with a >50% predicted risk of BPD had less harm associated with dexamethasone than did those at lower risk for BPD.[21] In practice, dexamethasone is usually delayed until infants are several weeks old, ventilator dependent, and require a high amount of oxygen therapy (>40%), and then the dose and duration should be minimized. A short-course (10-day), low-dose dexamethasone therapy (cumulative 0.89 mg/kg) has been shown to significantly decrease the duration of intubation and was not associated with long-term neurodevelopmental impairment in ventilator-dependent ELBW infants (the Dexamethasone: A Randomized Trial [DART]) study).[29] Therefore, dexamethasone 0.15 mg/kg/day in two divided doses for 3 days followed by 0.1 mg/kg/day for 3 days, 0.05 mg/kg/day for 2 days, and 0.02 mg/kg/day for 2 days may be considered for J.T., even though she is now 5 weeks old.[29] Throughout therapy, J.T. should be monitored for hyperglycemia, hypertension, GI bleeding, and intestinal perforation. With the increased use of noninvasive forms of assisted ventilation such as NIPPV, more infants are prescribed systemic corticosteroids to avoid intubation or BPD.[26]

Inhaled Corticosteroids

To decrease adverse effects associated with systemic administration, inhaled steroids such as beclomethasone dipropionate, fluticasone, and budesonide have also been used for the treatment and prevention of BPD.[30] When compared to placebo, inhaled corticosteroids were shown to significantly decrease the incidence of BPD and the combined outcome of death or BPD at 36 weeks' PMA, and the use of systemic steroids. No differences were found with BPD and the combined death or BPD at 28 days' PNA, duration of mechanical ventilation and oxygen therapy, and the incidence of CP.[30] When compared to systemic steroids, no significant differences in the incidence of BPD at 36 weeks' PMA or combined death or BPD at 36 weeks were found.[26] Although the use

of early inhaled steroids (ie, prevention) was associated with increased duration of mechanical ventilation and oxygenation, these findings were significantly different when compared with the use of late inhaled versus systemic steroids.[26] Long-term neurodevelopmental outcomes assessed at age 7 years were not significantly different between inhaled versus systemic steroids.[30] Studies evaluating other methods of inhalational administration of steroids (eg, instillation of steroid using surfactant as a vehicle) have reported conflicting results on the incidence of death and BPD.[24]

Adverse effects of inhaled steroids are less common than with systemic steroids; these include mild adrenal suppression, bronchospasm, tongue hypertrophy, and oral candidiasis.[2,26,30] Inhaled steroids may suppress the pituitary–adrenal axis; however, studies have reported conflicting results. Suppression may vary depending on the type of inhaled steroids, dosing regimen, and other factors such as prematurity. The infant's mouth should be cleaned after each use of inhaled steroid to minimize complications such as oral thrush. As with inhaled bronchodilators, administration is a therapeutic problem with these medications. Further studies evaluating the optimal dose, duration of therapy, time of initiation, delivery technique, most appropriate preparation, and long-term adverse effects (including neurodevelopmental outcome) of corticosteroids are needed before inhaled steroids can be routinely recommended.

Long-Term Sequelae

Case 105-2, Question 4: Five months have passed, and J.T. is now 5 weeks old (corrected age), weighs 3 kg, and is ready for discharge. During the past several months, ventilation requirements slowly decreased, and J.T. was eventually extubated. However, she still requires supplemental oxygen at an F_{IO_2} of 30%, 0.25 L/minute via nasal cannula, to maintain an oxygen saturation of 90% to 95%. What are the long-term complications of BPD that can be expected in J.T.?

Infants with BPD have little pulmonary reserve and, therefore, are at higher risk for experiencing frequent respiratory exacerbations. BPD places J.T. at risk for recurrent infections of the lower respiratory tract, and she may require frequent hospitalizations during the first year for bronchiolitis and pneumonia. Approximately 50% of all children with BPD require hospitalization for respiratory exacerbations during the first 2 years of life.[21] Respiratory syncytial virus is a common cause of respiratory distress and recurrent atelectasis. With time, most preterm survivors with BPD have an improvement in pulmonary function owing to lung growth; however, many continue to have airway hyperreactivity. Infants with severe BPD can also experience pulmonary hypertension, cor pulmonale, systemic hypertension, and left ventricular hypertrophy.[21,23]

In addition, J.T. may be at risk for experiencing bone demineralization and rickets. VLBW infants are born with inadequate stores of vitamin D. In general, these premature infants may not receive an adequate intake of vitamin D, either parenterally or through their diet. Most VLBW infants require prolonged parenteral nutrition, which may cause cholestasis or hepatic failure. Prolonged cholestasis or chronic hepatic congestion owing to heart failure may cause malabsorption of calcium and vitamin D. In addition, furosemide may exacerbate calcium deficiencies by causing hypercalciuria. These combined factors may result in bone demineralization and rickets. Infants with BPD usually have high catabolism and increased oxygen consumption as a result of the increased work of breathing and chronic hypoxia. Inadequate nutritional support may negatively affect weight gain, growth, and long-term outcome of BPD.

Neurologic and developmental abnormalities such as learning disabilities, speech delays, vision and hearing impairment, and poor attention span can also occur in infants with BPD.[21,23] BPD itself is not an independent risk factor for neurologic abnormality; related factors include BW, GA, and socioeconomic status.[21,23] Long-term follow-up evaluations at ages 1 to 15 years in infants previously treated with high-dose dexamethasone revealed an increase in neurodevelopmental abnormalities such as CP and decreased

school performance in some studies.[28] However, it is not known whether these abnormalities were attributable to an adverse effect of dexamethasone on brain development or to an improved survival of infants who may already be at risk for experiencing these abnormalities.

Mortality rates for infants with BPD are highest in those with severe BPD. Those with a diagnosis of pulmonary hypertension after a few months of life have a mortality rate as high as 40% to 50%.[21] The majority of deaths associated with BPD occur during initial hospitalization and are attributable to respiratory failure, sepsis, pneumonia, cor pulmonale, and congestive heart failure.[21,23]

Prevention

Case 105-2, Question 5: What preventive measures could have been used to decrease the likelihood of the development of BPD in J.T.?

Prevention of prematurity and other etiologic factors of RDS is the most effective means of preventing BPD. Although both antenatal steroids and exogenous surfactant therapy have been shown to reduce the incidence of RDS, the incidence of BPD has not been affected.[21,23,24]

Treatment with caffeine for apnea of prematurity is the best evaluated therapy for the prevention of BPD. The Caffeine for Apnea of Prematurity (CAP) trial demonstrated that early use of caffeine (initiated before 3 days of life) in infants with BW of 0.5 kg to 1.25 kg reduces the risk of BPD; however, this was a secondary outcome.[20,21,24] It also reduces the duration of mechanical ventilation and oxygen therapy. In addition to these short-term benefits, caffeine was also associated with a decreased incidence of neurodevelopmental impairment, including CP at ages 18 to 21 months. However, improved rate of survival without disability was not seen at 5 years.[20]

One of the causes of BPD can be vitamin A deficiency, which can predispose infants to BPD owing to impaired lung healing, increased

susceptibility to infection and loss of cilia, and decreased number of alveoli.[31] Premature infants, especially VLBW infants, are at the greatest risk owing to low body stores, inadequate intake during feedings, and decreased enteral absorption of vitamin A. Intramuscular (IM) vitamin A alone (<29 weeks' gestation) or given in combination with nitric oxide (BW 0.75–1 kg) has been shown to significantly reduce the combined outcome of mortality or BPD; however, no difference was found with mortality, ROP, or sepsis.[24] Long-term follow-up at age 2 years reported no significant difference in the incidence of neurodevelopmental disability.[31] Vitamin A seems to be well tolerated; the incidence of adverse effects was similar between treated and control groups. Although evidence appears to support IM vitamin A, further studies evaluating the efficacy, safety, and optimal dosage regimen of vitamin A for the prevention of BPD are needed. Furthermore, owing to the lack of availability, need for frequent IM administration, and high cost, the usage of vitamin A has declined over recent years. Oral vitamin A does not decrease the incidence of BPD, perhaps because of inadequate dose or poor absorption.[31]

Ureaplasma urealyticum colonization of the respiratory tract of premature infants is a significant risk factor for BPD. Several studies evaluated the use of macrolide antibiotics for eradication of *Ureaplasma* in premature infants at risk for BPD.[23,31,32] Studies evaluating macrolide use in infants for BPD prevention reported variable efficacy results.[31] Azithromycin and clarithromycin have demonstrated a slight improvement in BPD prevention, especially in infants with a positive result for *Ureaplasma*.[31,32] However, there is significant variability in sample size, definitions of BPD, and duration of treatment among these studies.[32] A recent study examining a 3-day course of IV azithromycin 20 mg/kg/day given within the first 3 days of life failed to find a significant decrease in BPD and mortality; however, infants treated with azithromycin had a significantly higher rate of *Ureaplasma*-free survival compared to placebo.[32] Although results may be promising, azithromycin has serious GI toxicity. Prolonged antibiotic exposure has been linked to an increased rate of necrotizing enterocolitis (NEC), sepsis, and fungal infections. In

addition, erythromycin and azithromycin use has been associated with infantile hypertrophic pyloric stenosis. An epidemiology study with >10 million infants reported an eightfold increased risk associated with azithromycin.[2,31] Therefore, owing to these adverse findings and conflicting clinical efficacy, routine use of macrolide antibiotics is not recommended.

Optimization of nutritional support may also help prevent the development of BPD because proper nutrition helps promote lung maturation, growth, and repair. Excessive fluid administration should be avoided because it may lead to BPD. Fluid restriction decreases both the incidence of BPD and mortality.[23] Fluid restriction, the early use of caffeine citrate, and IM vitamin A could have been recommended for J.T. in the early course of her hospitalization to help decrease the likelihood of her experiencing BPD.

PATENT DUCTUS ARTERIOSUS

The fetus has three unique circulatory structures that differ from the adult circulation: (a) the ductus venosus, which permits blood to bypass the liver; (b) the foramen ovale, which allows blood to pass from the right atrium into the left atrium; and (c) the ductus arteriosus, the structure that connects the pulmonary artery to the descending aorta and allows blood to bypass the lungs (**Fig. 105-1**).[33] In addition to these structural differences, vascular resistance and pressure play important roles in determining the pathway of the fetal circulation. For example, the relative hypoxia that occurs in utero causes pulmonary vasoconstriction. Pulmonary vasoconstriction, along with compression of pulmonary blood vessels by unexpanded fetal lung mass, results in a high pulmonary vascular resistance and decreased pulmonary blood flow. This decreased pulmonary blood flow is acceptable in utero because the lungs essentially are nonfunctional. Instead, gas exchange occurs through the placenta.

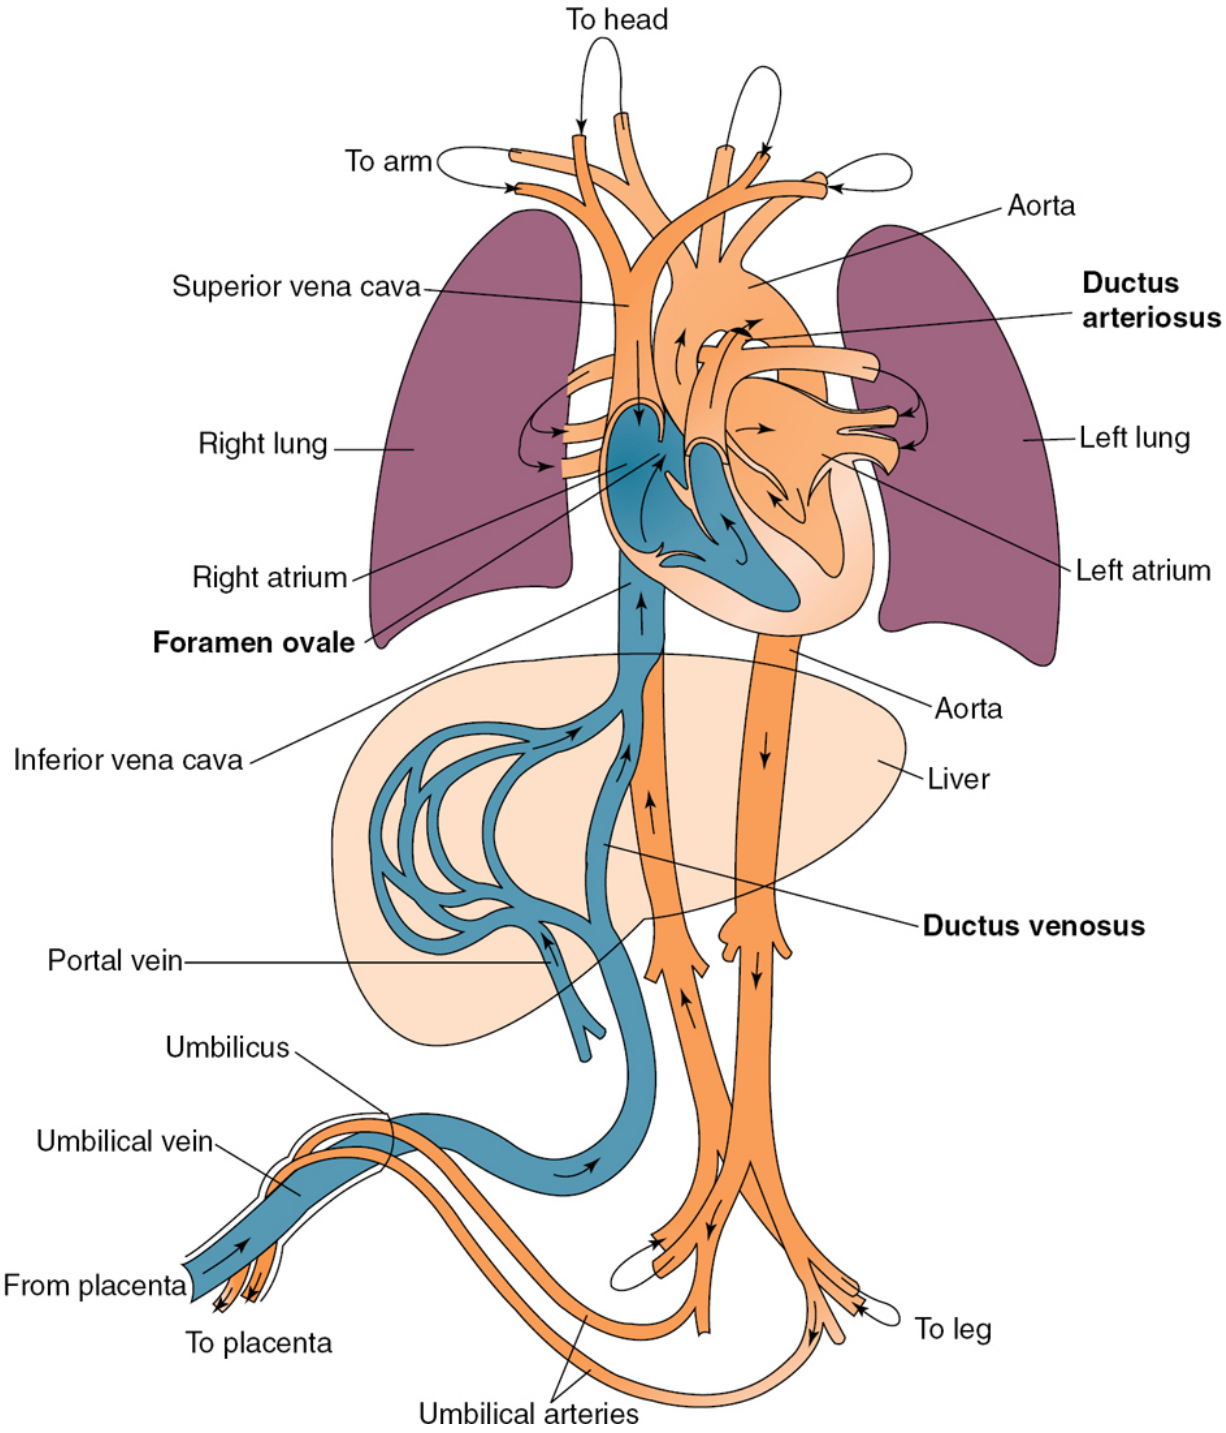

Figure 105-1 Fetal circulation. (Reprinted with permission from Pillitteri A. *Maternal and Child Health Nursing: Care of the Childbearing and Childrearing Family*. 7th ed. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

Maximally oxygenated blood (P_{O_2}, 30–35 mm Hg) flows from the placenta to the fetus through the umbilical vein (see Fig. 105-1). Approximately 50% of the umbilical venous blood is shunted away from the liver through the ductus venosus and directed into the inferior vena cava. Blood from the inferior vena cava and superior vena cava then enters the right atrium. Most of the blood from the inferior vena cava, which is well oxygenated, is directed in a straight pathway across the right atrium through the foramen ovale directly into the left atrium. It then enters the left ventricle through the mitral valve and is pumped through the ascending aorta and into the vessels of the head and forelimbs. Thus, the fetal brain is preferentially perfused with blood containing a higher amount of oxygen. Deoxygenated blood returning from the head region via the superior vena cava enters the right atrium and is directed through the tricuspid valve into the right ventricle, where it is then pumped into the pulmonary artery. Most of this blood is diverted through the ductus arteriosus into the descending aorta and then through the two umbilical arteries to the placenta. A small percentage of the blood flows to the lower extremities and then is returned to the heart via the inferior vena cava.[33]

Changes at Birth

At birth, major circulatory changes result from umbilical cord clamping, aeration and expansion of the lungs, and an increase in arterial P_{O_2}. These changes are important in the transition from a fetal to an adult circulation. An increase in systemic vascular resistance increases aortic, left ventricular, and left atrial pressures and cardiac output. Pulmonary pressures and blood flow also change. After the neonate's first breath, the lungs expand, oxygenation improves, and pulmonary vascular resistance immediately drops. This increases pulmonary blood flow, causing a decrease in pulmonary arterial, right ventricular, and right atrial pressures.[33]

Closure of the Foramen Ovale

After birth, pressure in the left atrium exceeds the pressure in the right atrium causing the small, valve-like flap that lies over the foramen ovale on the left side of the atrial septum to close over the foramen ovale opening. Closure of this flap prevents further flow through the foramen ovale.

Closure of the Ductus Arteriosus

Closure of the ductus arteriosus is more complex and depends on many factors. In utero, patency of the ductus arteriosus is maintained through the combined vasodilatory effects of a low P_{O_2} and high concentrations of prostanoids, particularly prostaglandin E_2 (PGE_2) and prostacyclin.[34] After birth, the smooth muscles of the ductus arteriosus constrict as arterial oxygenation increases and concentrations of placentally derived prostaglandins, particularly PGE_2, decrease.[34] Normally, the ductus arteriosus of a term neonate functionally closes within the first few days of life (ie, in 82% of infants within 48 hours of life and in 100% of infants within 96 hours of life). Anatomic closure of the ductus occurs within 2 to 3 weeks of life. When the ductus arteriosus fails to close, it is called *patent ductus arteriosus (PDA)*. In a term neonate, a PDA beyond the first few days of life generally is permanent. It usually is secondary to an anatomic defect in the wall of the ductus arteriosus and requires surgical intervention. In contrast, a PDA in a preterm neonate may persist for weeks and still close spontaneously.

When a PDA is present, the direction and amount of blood shunting through this opening are determined by the pressure gradient between the systemic and pulmonary circulations. Because systemic vascular resistance and aortic pressure are increased, and pulmonary vascular resistance and pulmonary arterial pressure are decreased after birth, blood pumped from the left ventricle into the aorta flows from the aorta (a high-pressure area) through the PDA and into the pulmonary artery (a lower pressure area). This flow is

called left-to-right shunting and is in contrast to the right-to-left shunting that occurs through the ductus arteriosus during fetal life.

Clinical Presentation

CASE 105-3

Question 1: T.S. is a 0.75-kg female who was born at 25 weeks' GA to a 22-year-old gravida 2 para 1 female. One hour after birth, T.S. exhibited symptoms of RDS, and two doses of beractant were given within the first 24 hours of life. After the second dose of beractant, T.S.'s respiratory function greatly improved, and no further doses of beractant were required. On the seventh day of life, the nurse noticed that T.S. had tachycardia, a systolic murmur, a hyperactive precordium, and a widened pulse pressure. Her lungs sounded "wet." In addition, the nurse noted that T.S.'s combined IV fluid rates total 160 mL/kg/day instead of the desired fluid intake of 120 mL/kg/day. Current vital signs and ABGs are as follows:

HR, 190 beats/minute
RR, 65 breaths/minute
BP, 55/23 mm Hg
O_2 saturation, 89%
pH, 7.22
P_{CO_2}, 55 mm Hg
P_{O_2}, 77 mm Hg
Base deficit, 10

Ventilator support is increased to compensate for T.S.'s deteriorating respiratory status. Echocardiography is performed and shows a moderate-size PDA with significant left-to-right shunting. The chest radiograph shows pulmonary edema and an enlarged heart.

What risk factors for PDA does T.S. have?

T.S. has two major risk factors for developing a symptomatic PDA: prematurity and RDS. The occurrence of a PDA is inversely proportional to GA and BW. The incidence of PDA is ~45% in premature infants with a BW of 1.75 kg, but can be as high as 80% in premature infants with a BW of <1.2 kg.[35] In contrast, the incidence of PDA in term infants is only 0.06%.[35] Preterm neonates are at a higher risk for PDA than are term newborns because the

smooth muscle of the immature ductus is more sensitive to the dilatory effects of prostaglandins and less sensitive to the constrictive effects of increased oxygen tension. In addition, circulating concentrations of PGE_2 are often elevated in premature infants owing to the decreased pulmonary metabolism of prostaglandins. These factors contribute to the delayed closure of the ductus arteriosus in premature infants.[34]

RDS also increases the risk of PDA. Exogenous surfactant also may increase the risk and lead to an earlier clinical presentation of symptomatic PDA.[34] PDA can further complicate the course of RDS.[34] T.S.'s course is typical of a preterm neonate with resolving RDS. T.S.'s pulmonary function improved after surfactant administration. Consequently, pulmonary vascular resistance decreased and the degree of left-to-right shunting across the ductus arteriosus increased, causing a deterioration in respiratory status. In addition, the excess fluid that T.S. received is an iatrogenic factor that may have increased the shunting across the PDA, aggravating the degree of pulmonary congestion.[34]

Case 105-3, Question 2: How is T.S.'s presentation consistent with that of PDA?

T.S.'s clinical presentation is related to the increased pulmonary blood flow, decreased systemic perfusion, and left ventricular volume overload that resulted from the shunting of left ventricular cardiac output through the PDA into the lungs. To compensate for the inadequate peripheral perfusion, HR increases. This results in an increase in cardiac output and a greater left-to-right shunt through the PDA, creating a vicious cycle. The widened pulse pressure (the difference between systolic and diastolic pressures, 32 mm Hg) is a result of the diversion of aortic blood flow through the PDA, which is causing the bounding pulses. The systolic murmur, which is not always present, is the result of turbulent blood flow through the ductus arteriosus occurring because the pulmonary vascular resistance decreases. Tachycardia, hyperactive precordium, and a

continuous murmur are results of the left-to-right shunting through the ductus arteriosus during systole.[36]

Case 105-3, Question 3: What are the potential complications of this hemodynamically significant PDA in T.S.?

The increased pulmonary blood flow and resultant pulmonary edema will worsen T.S.'s respiratory disease and increase the need for ventilatory support. The higher ventilatory settings (increase in mean arterial pressure [MAP] and FIO_2) place T.S. at risk for having BPD. If the PDA is left untreated, T.S. may experience congestive heart failure secondary to an increased left ventricular end-diastolic volume. A hemodynamically significant PDA also places T.S. at risk for IVH and NEC.[34]

Treatment

Case 105-3, Question 4: How should T.S.'s PDA be managed?

The initial medical management for T.S.'s symptomatic PDA is supportive care, which includes fluid management (eg, fluid restriction and diuretic therapy), correction of anemia, and treatment of hypoxia and acidosis. Although excessive fluid administration may increase the risk of PDA, fluid restriction alone is unlikely to result in ductal closure. T.S.'s fluid intake should be restricted to 100 to 120 mL/kg/day (~80% of total fluid maintenance requirements) to avoid worsening of her pulmonary edema and to prevent congestive heart failure.[34] Furosemide 1 mg/kg IV could be considered for administration to T.S. to treat her pulmonary edema. Because of T.S.'s GA, BW, and size of PDA, it is unlikely that she will respond to these general measures alone. Therefore, T.S. requires pharmacologic treatment with indomethacin or ibuprofen.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Both indomethacin and ibuprofen are available in injectable form for the treatment of PDA. These drugs nonspecifically inhibit prostaglandin synthesis, thereby eliminating the vasodilator effects of the PGE series on the ductus arteriosus, allowing the ductus to close. Indomethacin has been used clinically for >30 years for the treatment of PDA. However, because of its adverse effects, other prostaglandin inhibitors, such as ibuprofen, have been studied for PDA closure. Ibuprofen is as effective as indomethacin in closing the ductus and causes significantly less of a decrease in renal, mesenteric, and cerebral blood flow. Thus, ibuprofen reduces the risks of NEC and transient adverse effects on renal function (eg, oliguria, elevations of serum creatinine [SCr]) compared with indomethacin.[37] Hyperbilirubinemia is more common with ibuprofen. However, the incidence of mortality, BPD, and IVH are similar for both drugs. Unfortunately, no long-term follow-up studies of ibuprofen exist. These studies are needed to determine whether ibuprofen or indomethacin is the drug of choice for PDA closure.[37] Based on the studies currently available, ibuprofen may be preferred in patients who have or are at risk for decreased renal function. The initial dose of ibuprofen lysine is 10 mg/kg followed by two doses of 5 mg/kg given at 24-hour intervals. If urinary output decreases to <0.6 mL/kg/hour, the second or third doses should be held.[2]

Unfortunately, not every infant treated with a nonsteroidal anti-inflammatory drug (NSAID) responds with constriction of the ductus arteriosus; therefore, surgical closure (eg, ligation, coiling) of the PDA may be required. Surgery generally is reserved for neonates who do not respond to pharmacologic therapy or those in whom drug therapy is contraindicated.[34]

Case 105-3, Question 5: Owing to lower risks of adverse effects on renal function, the attending physician would like to treat T.S. with ibuprofen for closure of her PDA. You explain to the medical team that there is a temporary shortage of ibuprofen, and, therefore, T.S. should be treated with indomethacin. The medical team then asks the following: What is the dose of indomethacin for T.S.? What route should be used for its administration?

The medical team should be told the following information. The route of choice for indomethacin is IV in the United States. In developing countries, enteral NSAIDs have been shown to be effective. However, there are concerns for increased GI side effects.[38]

A large interpatient variability of indomethacin pharmacokinetics occurs in preterm neonates. Serum concentrations do not correlate consistently with therapeutic or adverse effects. Furthermore, the optimal therapeutic serum concentration is not yet defined.[39] The most commonly used regimen involves three indomethacin doses, given in 12- to 24-hour intervals, with the first dose equal to 0.2 mg/kg IV in all neonates.[2] Because indomethacin clearance is directly proportional to PNA, the second and third doses are determined by PNA at initiation of indomethacin therapy. If onset of treatment was at <2 days' PNA, neonates receive 0.1 mg/kg/dose; if initiation of therapy occurred at 2 to 7 days' PNA, neonates receive 0.2 mg/kg/dose; if therapy began at >7 days' PNA, neonates receive 0.25 mg/kg/dose. The second and third doses are administered at 12- to 24-hour intervals. No specific guidelines exist regarding which patients receive every-12-hour versus every-24-hour dosing; however, the individual dosing interval generally is determined by the neonate's urine output. If urine output remains >1 mL/kg/hour after an indomethacin dose, then the next dose may be given in 12 hours. If urine output is <1 mL/kg/hour but >0.6 mL/kg/hour, then the dosing interval may be extended to 24 hours. Doses should be held if urine output is <0.6 mL/kg/hour. T.S. should receive three doses of indomethacin 0.15 mg (0.2 mg/kg/dose) given every 12 hours, as long as her urine output remains >1 mL/kg/hour. If T.S.'s urine output decreases, then the dosing interval should be adjusted as outlined earlier. Because rapid IV administration of indomethacin can decrease cerebral, mesenteric, and renal blood flow, longer infusion rates of 20 to 30 minutes are recommended.[2,40]

Response to NSAID therapy can be determined by assessing the clinical signs of PDA such as tachycardia, widened pulse pressure, bounding pulses, heart murmur, and the ability to wean from

ventilator support. In certain cases, echocardiography may be performed to confirm the closure of a PDA.

Case 105-3, Question 6: What clinical and laboratory data should be monitored during T.S.'s indomethacin therapy?

Before initiating indomethacin therapy, T.S. should receive an echocardiogram to rule out ductal-dependent congenital heart disease and to confirm the presence of a PDA. In addition, an SCr and blood urea nitrogen (BUN) should be obtained from T.S. before indomethacin therapy because nephrotoxicity is the most common adverse effect. Infants receiving indomethacin can experience transient oliguria with increased SCr. This occurs as a result of indomethacin-induced decreases in renal blood flow and glomerular filtration rate.[40] Dilutional hyponatremia may occur secondary to decreased urine output. Treatment of hyponatremia should be aimed at decreasing free water intake through fluid restriction rather than by sodium supplementation. Typically, renal function normalizes within 72 hours of the last dose of indomethacin. In general, indomethacin therapy is contraindicated in neonates with renal failure, urine output <0.6 mL/kg/hour, or an SCr of ≥1.8 mg/dL.[2]

In addition to monitoring renal function and serum electrolytes, serum concentrations of aminoglycosides, digoxin, and other renally eliminated drugs should be monitored carefully. Indomethacin therapy may decrease renal drug clearance and cause accumulation of these agents, which may require a dosage reduction.[41]

A platelet count should also be obtained from T.S. before therapy because indomethacin may decrease platelet aggregation. Thrombocytopenia (platelet count < 50,000–60,000/μL) is a contraindication to indomethacin therapy.[2,40] In cases of thrombocytopenia, indomethacin may be withheld temporarily until platelets can be transfused. Other potential contraindications to indomethacin therapy include active bleeding and clinical evidence of NEC because GI bleeding, perforation, and NEC have been reported with indomethacin use.[34,40] These GI effects may be related

to decreases in intestinal blood flow usually seen with rapid IV infusions. Grades II to IV IVH also are frequently quoted as contraindications to indomethacin therapy; however, indomethacin treatment probably is not associated with the progression of IVH. In fact, prophylactic treatment with indomethacin may be associated with a decrease in the incidence of severe IVH (grades III and IV).[34,40]

Case 105-3, Question 7: When is the best time to initiate an NSAID for symptomatic treatment of T.S.'s PDA?

Controversy about the optimal timing for PDA closure has existed since the first report of ligation of the ductus arteriosus four decades ago. Some centers may opt to pharmacologically treat within the first week of life when a PDA is initially detected despite a lack of symptoms. This approach results in unnecessary drug exposure in neonates who would experience spontaneous closure without pharmacologic intervention, and thus is not recommended.[40] Others may not treat until symptoms of a PDA are present (early, within 5 days of life; late, 7–14 days of life). Both treatment strategies (early and late symptomatic) significantly decrease the incidence of PDA, but both cause significant transient reduction of urine output and SCr elevation.[40] Conflicting data regarding the short- and long-term benefits of ductal closure (indomethacin or ibuprofen) including the effect on complications (eg, BPD, NEC, IVH) and mortality continue to result in varied clinical practices and a lack of a standard of care.[42] Because T.S. is an ELBW neonate with RDS, she is at high risk for complications associated with a large PDA. She also has clinical signs of a PDA and, thus, many practitioners would consider treating her PDA at this time.

Case 105-3, Question 8: The physicians were able to decrease T.S.'s ventilator support within the first 12 to 24 hours of starting indomethacin treatment. After 3 to 4 days of gradual and consistent ventilator weaning, the ventilator settings could not be decreased further. During the next 2 to 3 days, T.S.'s respiratory status deteriorates, and she requires increased ventilator

support. T.S. now has tachycardia, a widened pulse pressure, bounding pulses, and a hyperactive precordium. Repeat echocardiogram shows a small-to-moderate PDA. Current data include the following:

BUN, 10 mg/dL
SCr, 1.1 mg/dL
Sodium, 134 mEq/L
Potassium, 4.9 mEq/L
Chloride, 97 mEq/L
Urine output, 2.3 mL/kg/hour
Fluid intake, 130 mL/kg/day
Platelets, 180,000/μL

Why did PDA recur in T.S., and how should it be managed?

Successful closure of the PDA with indomethacin occurs in 70% to 90% of infants; however, ductal reopening or recurrence can occur.[34] Recurrence of PDA occurs especially in lower BW infants. Several reasons might explain T.S.'s transient response to indomethacin. Recurrence of PDA is inversely proportional to GA; the incidence of ductal reopening is significantly higher in infants with 26 weeks' GA or younger compared with infants born at 27 weeks' gestation or more (20% vs 9%, respectively).[34] The higher recurrence in younger GA neonates may be related to resumption of PGE_2 production after indomethacin serum concentrations decline and heightened sensitivity of the immature ductus arteriosus to the dilating effects of PGE_2.[34]

Furthermore, the rate of recurrence is lower in infants who were treated with indomethacin earlier in life compared with those who receive treatment later.[34] Because anatomic closure of a PDA may be delayed for a couple of weeks, it is not surprising that the ductus arteriosus reopened in T.S. after her initial response to indomethacin.

Prolonged indomethacin therapy may prevent recurrences and allow for permanent closure of the ductus arteriosus. However, prolonged courses of indomethacin are associated with a significantly higher incidence of NEC, so their routine use is not recommended.[34] The optimal timing, duration, and dosing regimen of indomethacin, as well as the subset of neonates most likely to benefit from therapy still need to be identified.

T.S. remains ventilator dependent and is at increased risk for exhibiting BPD. Because she has no contraindications to indomethacin therapy, a second course of indomethacin could be considered, although the incidence of successful closure with repeated courses is significantly lower compared with the initial course.[43] If the PDA fails to respond to this prolonged regimen or if it recurs again after an initial response, and T.S. remains ventilator dependent, surgical closure most likely will be required to permanently close the PDA.

Prophylactic Administration

Case 105-3, Question 9: Could prophylactic NSAID administration have prevented the development of a symptomatic PDA in T.S.?

Prophylactic indomethacin therapy is defined as the administration of indomethacin within 24 hours of life to newborns who are at risk for experiencing a symptomatic PDA.[40] However, routine prophylaxis would unnecessarily expose a large number of newborns to indomethacin (and its adverse effects) because PDA closure may occur spontaneously without treatment. Prophylactic use of indomethacin has short-term benefits; it significantly decreases the incidence of PDA and IVH (grades III and IV) and the need for PDA surgical closure.[44] Unfortunately, most studies have not shown that prophylactic ductal closure with indomethacin decreases the incidence of death, BPD, NEC, or neurodevelopmental disabilities. In addition, infants receiving prophylactic therapy have a higher incidence of severe oliguria or anuria, albeit transient.[44] Therefore, routine prophylactic administration is usually not warranted. It may be considered, however, in some neonatal units that do not have easy access to cardiac diagnostic and therapeutic services or those that have a high incidence of IVH.

Prophylactic ibuprofen therapy (administered at <24 hours of life) decreases the incidence of PDA and the need for rescue pharmacologic treatment and surgical closure.[45] However, it does not

appear to decrease BPD, IVH, NEC, or mortality, and may increase the risk of renal dysfunction and GI bleeding. Because of the lack of long-term follow-up studies with the current ibuprofen lysine product, prophylactic ibuprofen therapy for the prevention of PDA is not recommended at this time.

Treatment With Acetaminophen

Case 105-3, Question 10: During multidisciplinary neonatal intensive care unit (NICU) rounds, the advanced nurse practitioner mentions that acetaminophen has been used to treat PDA and it may be safer than NSAIDs. Should acetaminophen, rather than indomethacin, have been used to treat the symptomatic PDA in T.S.? What is the evidence to support its use?

The advanced nurse practitioner is partially correct and should be informed of the following information. Several case reports and studies suggest that acetaminophen may be used for the treatment of PDA.[40,45] Similar to NSAIDs, acetaminophen inhibits prostaglandin synthesis. However, in contrast to NSAIDs that inhibit cyclooxygenase-1 and -2 (steps that occur early in the synthesis of prostaglandins), acetaminophen is thought to affect a subsequent step in prostaglandin synthesis by inhibiting the peroxidase site of the enzyme, prostaglandin synthetase.[40] Owing to the different mechanisms of actions, acetaminophen would be expected to have less serious side effects than do NSAIDs.

Acetaminophen at doses of 15 mg/kg every 6 hours for 2 to 7 days has been compared to indomethacin and ibuprofen for the treatment of PDA in preterm neonates.[46,47] There is no significant difference in the failure rates for PDA closure or risk of reopening the PDA between the three drugs. No significant differences in secondary outcomes or adverse effects were observed, with a few exceptions: SCr and bilirubin levels were significantly lower, and platelet counts were higher in patients who received acetaminophen. Although these results appear promising, an association of prenatal and postnatal use of acetaminophen with autism or autism spectrum

disorder has been identified.[47] In addition, animal studies suggest that acetaminophen may affect cognitive function when administered during neonatal brain development. Therefore, further research, including long-term follow-up studies of neurodevelopment, is needed before acetaminophen can be recommended for PDA closure in routine clinical practice.[47] Owing to these concerns, acetaminophen should not have been used in place of indomethacin to treat the symptomatic PDA in T.S. After weighing all potential risks and benefits, some clinicians may use acetaminophen before surgical closure in select neonates with a significant PDA, who have failed or who have contraindications to NSAID therapy.

NECROTIZING ENTEROCOLITIS

CASE 105-4

QUESTION 1: C.D., an 18-day-old female neonate (current weight 0.98 kg), was born at 27 weeks' GA with a BW of 0.86 kg. Her postnatal course has been complicated by RDS, sepsis, and a large PDA for which she required intubation and mechanical ventilation, one dose of beractant, a 7-day course of ampicillin and gentamicin, and indomethacin. Enteral feedings with a standard preterm 24-cal/oz formula were started on day 4 of life at 5 mL every 3 hours (~46 mL/kg/day). Feedings were increased by 5 mL/feed on days 5 through 7 to 18 mL/feed every 3 hours on day 7 of life (~170 mL/kg/day). This morning, C.D. exhibited a distended abdomen, bloody stools, multiple episodes of apnea that required reintubation and assisted ventilation, and metabolic acidosis. ABG results revealed the following:

pH, 7.15
P_{CO_2}, 67 mm Hg
P_{O_2}, 55 mm Hg
Base deficit, 10

An abdominal radiograph revealed pneumatosis intestinalis (the presence of gas in the intestinal submucosa). C.D. is to take nothing by mouth (NPO), and gentamicin 5 mg/kg IV infusion every 36 hours and ampicillin 100 mg/kg IV push every 8 hours are restarted.

What clinical signs of NEC does C.D. have? What is the pathogenesis of NEC, and what risk factors for NEC does C.D. have?

NEC, a type of acute intestinal necrosis, is the most common neonatal life-threatening nonrespiratory condition in preterm infants. The incidence of NEC in VLBW infants ranges from 5% to 9% and is inversely proportional to GA and BW.[48] Approximately 90% to 95% of NEC occurs in premature infants, with the highest incidence between 28 and 33 weeks' PMA; however, NEC can infrequently occur in full-term neonates.[48,49] The age of onset of NEC is also inversely related to GA and BW; the greater the GA at birth, the sooner the onset of NEC. Although NEC is less common in term infants, it usually develops within 3 to 4 days of birth. In contrast, infants born at ~30 weeks' gestation acquire NEC at a mean PNA of 20 days compared to 13.8 days for infants born at 31 to 33 weeks and 5.4 days for those born after 36 weeks of gestation.[48] Thus, preterm infants are at risk for NEC for a longer time. Although C.D. is extremely premature, she experienced NEC early (at 18 days of age), most likely because of the aggressive advancement of feedings. NEC contributes to a significant morbidity and mortality, with surgical-managed infants at the highest risk. The overall mortality of NEC ranges from 20% to 30%, with 35% for surgical-managed infants compared to 21% for medical-managed infants.[49] In addition, NEC is also a significant economic burden to health care costs. Infants with NEC required longer hospitalizations compared with infants without NEC, with an estimated annual cost of 500 million to 1 billion U.S. dollars.[49]

C.D. has several clinical signs of NEC, including abdominal distension, bloody stools, apnea, metabolic acidosis, and pneumatosis intestinalis on abdominal radiograph. Gastric retention of feedings, respiratory distress, occult blood in stools, lethargy, temperature instability, thrombocytopenia, and neutropenia also may occur. NEC may progress to bowel perforation, peritonitis, sepsis, disseminated intravascular coagulopathy (DIC), and shock. On an abdominal radiograph, the presence of gas in the intestinal mucosa or in the portal venous system is diagnostic of NEC, and free air in the abdomen is observed with bowel perforation. Although these radiographic findings confirm the diagnosis of NEC, a lag time may

occur between the initial clinical signs of NEC and radiologic confirmation.[48–50]

NEC can evolve slowly during a period of 24 to 48 hours, from a clinically benign course to an advanced stage of shock, peritonitis, and widespread intestinal necrosis. Although NEC can affect any part of the GI tract, most of the disease is confined to the jejunum and ileum for preterm infants and to the colon for term infants.[48] A staging system, which categorizes severity according to systemic, intestinal, and radiologic signs, has been developed to permit a more consistent evaluation and treatment of patients.[48,49] Stages IA and IB NEC include neonates and infants with suspected disease or rule out NEC. These patients may have mild GI problems such as delayed gastric emptying and emesis, temperature instability, apnea, bright red blood from the rectum, or a mild ileus. Infants with stages IIA and IIB have definite NEC and usually present with abdominal distension, bloody stools, and the presence of pneumatosis intestinalis on radiograph. Infants in stage IIB NEC may also exhibit metabolic acidosis and thrombocytopenia. Infants with stages IIIA and IIIB (advanced disease) are severely ill with clinical signs, including peritonitis, ascites, shock, severe metabolic and respiratory acidosis, and DIC. Those with stage IIIB have intestinal perforation. Pneumatosis intestinalis, caused by hydrogen production from bacterial translocation into the bowel wall, is a classic and diagnostic radiographic finding of NEC. Because pneumatosis intestinalis may be hard to detect on radiographs, some infants can experience severe NEC and need surgery without having radiographic findings. Therefore, new criteria including biomarkers of NEC may be needed to help diagnose NEC sooner and prevent its progression. C.D.'s presentation is most consistent with stage IIB NEC.

The pathogenesis of NEC is unknown but seems to be multifactorial. Most likely, NEC results from the effects of intestinal bacteria and other factors on injured intestinal mucosa. Inflammatory mediators such as platelet-activating factor, tumor necrosis factor-α, and interleukin (IL)-1, IL-6, IL-8, and IL-10 may also contribute to mucosal damage.[49] The neonatal intestinal mucosa is prone to injury for the following reasons: (a) increased permeability to potentially

harmful substances, such as bacteria and proteins; (b) decreased immunologic host defenses, including low concentrations of immunoglobulin A in intestinal mucosa; and (c) decreased nonimmunologic defenses, such as decreased concentrations of proteases and gastric acid. Furthermore, inappropriate initial microbial colonization may also contribute to the pathogenesis of NEC in preterm neonates, especially because NEC does not occur until after 1 week of life, at a time when the gut has been colonized with anaerobic bacteria.[48–50] In addition, numerous factors (both prenatal and postnatal) can cause injury to the neonatal intestinal mucosa and increase the risk of NEC. Prenatal maternal factors include eclampsia, prolonged rupture of membranes, chorioamnionitis, placenta abruption, smoking, lack of antenatal steroids, maternal cocaine use, and cesarean section. Postnatal factors include prematurity, low BW, ischemia or hypoxemia, asphyxia, intrauterine growth restriction, hypotension, respiratory distress, severe anemia, malnutrition, infection, hemodynamically significant PDA, congenital GI anomalies, cyanotic heart disease, formula feeding, exchange transfusions, blood transfusions, and the presence of umbilical catheters.[48–50] Medications such as corticosteroids, indomethacin, and H_2-blockers and prolonged empiric IV antibiotic use have also been associated with an increased risk of NEC.[50] However, the most significant clinical risk factor for NEC is prematurity.[48–50]

C.D. has several risk factors for developing NEC, which include prematurity, ELBW, history of infection, and RDS requiring mechanical ventilation. Furthermore, C.D. not only was given a hyperosmolar formula (24 cal/oz instead of 20 cal/oz) but her feedings were also advanced aggressively. These two factors may also contribute to the development of NEC. More than 90% of infants with NEC have received enteral feedings, although NEC also occurs in infants who have never been fed.[49] Enteral feedings (breast milk or formulas) serve as substrates for bacterial proliferation in the gut. As a result, reducing substances, organic acids, and hydrogen gas are produced by bacterial fermentation of these nutrients.

Observational studies have shown that rapid advancements in the volume of feeds (30–40 mL/kg/day vs <24 mL/kg/day) were associated with an increased risk of NEC; however, these studies were not controlled and were small case series. In addition, slower feeding advancement has been associated with an increased risk of late-onset sepsis and a delay in reaching full enteral feeds.[51] A recent study reported that VLBW infants advanced at a rate of 30 mL/kg/day reach full enteral intake significantly earlier than did infants advanced at 18 mL/kg/day without increasing the risk of NEC, death, late-onset sepsis, or survival without moderate-to-severe neurodevelopmental disability at 2 years corrected age.[52] However, infants in the faster advancement group had a higher risk of moderate or severe motor impairment compared to the slower advancement group. NEC, death, late-onset sepsis, time to reach full enteral feedings, and moderate or severe motor impairment were secondary outcomes. In fact, infants who were fed earlier had a significant reduction in the number of days on parenteral nutrition.[52] C.D. was started at a much higher initial feeding volume (46 mL/kg/day) and aggressively increased by 46 mL/kg/day, which may have increased the risk of NEC. If C.D. were appropriately fed, she would have reached full feedings in 7 to 14 days instead of 4 days. Last, the presence of PDA and the use of indomethacin for the treatment of PDA may also have contributed to NEC in C.D. through decreased mesenteric blood flow with resultant ischemia and intestinal mucosal injury.[48,50]

Treatment

Case 105-4, Question 2: How should C.D. be managed?

Significant abdominal distension may compromise respiratory function and blood flow to the intestines. Therefore, as soon as NEC is suspected, feedings should be stopped immediately and an orogastric tube with low intermittent suction placed to decompress

the abdomen. C.D.'s vital signs and abdominal circumference should be closely monitored for disease progression. A complete blood count and platelet count should be obtained frequently to monitor for neutropenia and thrombocytopenia. Blood and urine cultures should be obtained, and parenteral antibiotics should be started as soon as possible; 25% of infants with NEC have associated bacteremia.[51] Radiographic examinations should be routinely performed at least every 4 to 8 hours or as needed to evaluate the progression of the disease. In infants with stage I NEC, antibiotic therapy is usually given for 3 days pending culture results and clinical signs. Once the diagnosis of NEC is ruled out, antibiotics may be discontinued. Enteral feedings can then be initiated slowly. However, if the diagnosis of NEC is made (ie, stage II or III), antibiotics are continued and parenteral nutrition is initiated. Infants require bowel rest (NPO) for at least 7 to 14 days. The length of antibiotic therapy and bowel rest in infants with documented NEC is determined by the severity of systemic illness (eg, metabolic acidosis, thrombocytopenia). In general, infants with NEC stage II require at least 7 to 10 days of antibiotic therapy and bowel rest, whereas those with NEC stage III may require at least 10 to 14 days. C.D. has stage IIB disease and needs to be NPO for at least 7 to 10 days; she requires total parenteral nutrition during that time, and the surgery team should be notified at this point. Infants with stage III disease may also require fluid resuscitation, administration of inotropic agents such as dopamine and dobutamine, and surgical intervention, especially for those with perforated NEC.[49,50] About 27% to 52% of VLBW infants treated for medically managed NEC require surgical intervention (either primary peritoneal drainage or exploratory laparotomy), with the absolute indication for surgery being intestinal perforation, suspected bowel necrosis, and failure to respond to medical treatment.[51] Despite the type of surgical intervention, up to 35% of infants who require surgery will die.[49]

Case 105-4, Question 3: C.D. just completed a 7-day course of ampicillin and gentamicin for presumed sepsis. Is it appropriate to restart these antibiotics?

The selection of antibiotics for NEC depends on the common microorganisms observed in an individual neonatal unit, their sensitivities, and the spectrum of antimicrobial activity against intestinal microorganisms. Many organisms have been implicated in NEC, including Enterobacteriaceae (eg, *Escherichia coli, Klebsiella* species), *Pseudomonas, Staphylococcus aureus* (in rare cases, methicillin resistant), *S. epidermidis, Clostridium,* and fungi, usually *Candida*.[53] For most cases of NEC, treatment consists of broad-spectrum antibiotics including ampicillin and gentamicin.

Other antibiotics used to treat NEC include combined ampicillin and cefotaxime or monotherapy with meropenem or piperacillin/tazobactam. Vancomycin may replace ampicillin for suspected methicillin-resistant *S. aureus* or ampicillin-resistant enterococcal infection. The combination of cefotaxime and vancomycin has been shown to prevent severe peritonitis and death and reduce the need for surgery in infants with BWs <2.2 kg with NEC, whereas gentamicin and ampicillin have not. Suppression of Staphylococcal fecal flora by the combination of cefotaxime and vancomycin may explain these findings.[53] Owing to the small sample size and low-quality observational study, the authors recommend vancomycin and cefotaxime in infants not responding to initial standard regimen. Further studies are needed to determine whether the combination of gentamicin and vancomycin would be superior to cefotaxime and vancomycin. C.D. was prescribed with ampicillin and gentamicin and should be treated for 7 to 10 days. If C.D. is not responding to ampicillin and gentamicin, consideration should be made to replace ampicillin with vancomycin and gentamicin with cefotaxime. Owing to the national shortage of cefotaxime, ceftazidime has replaced cefotaxime in many NICUs.

Case 105-4, Question 4: Two days later, C.D. exhibits peritonitis with ascites (NEC stage III), hypotension, worsening metabolic acidosis, neutropenia, and DIC. IV fluids and dopamine are administered for the hypotension, fresh-frozen plasma and whole blood are given to treat the coagulopathy, and a fentanyl continuous infusion at 1 µg/kg/hour is started for pain control. Free air in the

abdomen is observed on abdominal radiograph. Blood, urine, and stool cultures have had no growth for 48 hours. What additional antimicrobial coverage should be provided?

The use of empiric anaerobic coverage in infants with definite NEC, stage II or III, remains controversial; however, many institutions have added anaerobic coverage to routine antibiotic regimens.[49,51,53] The two most commonly used agents are clindamycin and metronidazole. Routine use of clindamycin in the treatment of NEC has not decreased the incidence of intestinal gangrene, perforation, or death. In addition, it has been associated with an increased incidence of abdominal strictures.[53] There are no studies to demonstrate the efficacy of metronidazole in this patient population, but the lack of reports documenting adverse effects in preterm infants has made it the agent of choice in some hospitals. A study utilizing a database from 348 NICUs assessed the association of anaerobic antimicrobial therapy and clinical outcomes in VLBW infants. The authors reported no significant difference in the incidence of the combined outcome of death or intestinal strictures in infants with NEC stages II and III treated with or without anaerobic coverage.[54] Furthermore, anaerobic antibiotic therapy did not prevent the progression to death within 7 days of NEC diagnosis or to surgical NEC. However, a higher risk of strictures was found in all infants receiving anaerobic antibiotic therapy. Furthermore, in those with surgical NEC, a lower mortality rate was found in the anaerobic antibiotic-exposed infants.[54]

Based on this study, it might be prudent to consider weighing the risk versus benefit when deciding to add anaerobic antibiotic therapy in the treatment of medically managed NEC. In contrast, infants with peritonitis secondary to intestinal perforation (ie, those needing surgery) require both aerobic and anaerobic coverage.[55] Therefore, an antimicrobial agent with anaerobic activity such as metronidazole (instead of clindamycin) should be added to C.D.'s current regimen. Because *Candida* is not uncommon in infants with NEC, an antifungal agent such as fluconazole or amphotericin B should be

added if a culture result is positive for fungi and/or there is clinical deterioration.

Appropriate antibiotic selection and duration of treatment of medical and surgical NEC are unknown and are usually determined by clinical status and nonspecific inflammatory laboratory markers such as C-reactive protein (CRP). One study found a high degree of variability in the antibiotic regimens prescribed in infants with surgical NEC. Ampicillin, gentamicin, and metronidazole were the most common pre- and postoperative antibiotic regimen with a mean duration of 10.6 days for preoperative and 6.6 days for postoperative NEC. There was no difference in clinical outcomes among the different antibiotic regimens and duration of therapy.[54] Owing to the concerns of antibiotic overusage in preterm infants, studies are needed to identify the optimal antibiotic regimen and duration of therapy for the treatment of medical and surgical NEC.

Complications and Prognosis

Case 105-4, Question 5: C.D. is taken urgently to the operating room, and 40 cm of necrotic ileum is removed along with the ileocecal valve. What are the long-term nutritional problems that C.D. is likely to have?

The most common postoperative complications of NEC are intestinal strictures (up to 25%) and short-bowel syndrome (11%).[48,49,51] C.D. is at risk for experiencing short-bowel syndrome, a condition of malabsorption and malnutrition that results from surgical removal of a significant portion of the small intestine. The most important factors that determine short-bowel syndrome are the length of the remaining small intestine and the presence of the ileocecal valve. Because C.D. has had a majority of her ileum and her ileocecal valve removed, she most likely will suffer from short-bowel syndrome.

Because the terminal ileum is an important site for absorption of vitamins, trace minerals, and nutrients, C.D. will be at risk for decreased absorption of these substances. C.D. also will have a

faster GI transit time and diarrhea because her ileocecal valve was removed. (The ileocecal valve plays a major role in controlling intestinal transit time.) Absorption of enterally administered medications also may be decreased in patients with short-bowel syndrome. When C.D. starts to receive most of her nutrition enterally, she should be monitored for fat malabsorption and other nutritional deficiencies (eg, deficiencies in vitamins A, B_{12}, D, E, and K), and supplemented accordingly.

Despite advances in earlier diagnosis and aggressive treatment, ~20% to 30% of all infants with NEC die, with the highest mortality in extremely premature infants and those with surgical NEC.[48,49] Furthermore, infants with NEC are significantly more likely to have neurodevelopmental impairment (eg, CP); those requiring surgical management are at higher risk.[49,51]

Prevention

Case 105-4, Question 6: What could have been done to prevent NEC in C.D.?

Several interventions may decrease the incidence of NEC. Enteral feedings in preterm infants can be withheld for several weeks and parenteral nutrition initiated. Although intestinal priming or trophic feeding (ie, using a small amount of full-strength formula or breast milk for several days to stimulate GI mucosal development) has been shown to decrease the incidence of NEC compared with infants with the advancement of feedings, a Cochrane review did not report an increased risk of NEC with infants NPO beyond 4 days of life.[49] Because human milk provides antibodies, growth factors, and cellular immune factors, it may reduce the incidence of NEC. Infants fed with human milk had a significantly lower incidence of NEC and bacteremia than those fed with formula.[48–51] If mother's milk is not available, pasteurized donor human milk has also been shown to significantly decrease the risk of NEC.[48] In a recent study, a

significant decrease in the incidence of NEC and surgical NEC was observed in infants who were exclusively fed with a human milk–based diet compared with a combination of human milk and formula-based diets.[49] Human milk fortifier can be added to human milk to provide appropriate caloric requirements to stimulate fetal growth. Ideally, avoid the use of hyperosmolar formulas or medications because they can cause osmotic injury to the bowel and may result in NEC. Maternal steroids (commonly used to accelerate fetal lung maturation) can decrease the incidence of NEC owing to a maturational effect on the microvillous membranes.

Probiotics are live, nonpathogenic microbial preparations that colonize the intestine and have a beneficial effect on the health of the host. Probiotic microorganisms commonly used are strains of *Lactobacillus* and *Bifidobacterium.* In a recent meta-analysis of >9000 preterm infants, enteral administration of probiotics significantly decreased the risk of severe NEC, death, and sepsis.[56] Multiple-strain probiotics were found to be superior to single-strain probiotics in decreasing the incidences of NEC, death, and sepsis, possibly because the normal flora in the gut is diverse. Furthermore, *Lactobacillus* and *Bifidobacterium* were found to be significantly associated with a reduced risk of NEC; however, this effect was not seen with *Bacillus* and *Saccharomyces.* Studies evaluating the long-term effects of probiotics (assessed at 18–22 months up to 3 years corrected age) reported no adverse effects on growth or neurodevelopmental outcomes.[56] One major concern is that exposing immunologically immature VLBW infants to probiotics may potentially increase the risk of infections. Cases of systemic infections, especially in ELBW neonates, have been reported.[56] Some cases of probiotic-associated sepsis may not be identified owing to the failure of the laboratory to isolate these strains in blood cultures by the use of conventional culture-based techniques. Other controversies exist. Most studies did not evaluate the effects of probiotics in ELBW infants, the population at greatest risk for NEC. The optimal type of probiotic (species, strains, single or combined, live or killed) and the timing, dosage, and duration of therapy are still unknown. Little is known regarding the benefits of probiotics in

infants who are exclusively or partially fed breast milk. Furthermore, none of the studies were conducted in the United States, and most of the trials did not utilize U.S. commercially available probiotics. Lastly, currently no product in the United States has the appropriate regulatory mechanisms in place to ensure the quality of the product. Therefore, clinical studies are needed to address these issues, and if probiotics are administered to VLBW infants for the prevention of NEC, careful surveillance of mortality, NEC, and the emergence of resistant strains will be necessary. Based on these findings, probiotics may be prescribed in NICUs with high rates of NEC because the benefit may outweigh the risk. When C.D. is ready to be fed, breast milk or donor breast milk (if available) should be used in place of formula to help prevent future risk of NEC. Because C.D. already has NEC, probiotics may not be beneficial to her at this time.

Other preventative strategies include the implementation of antimicrobial stewardship and a standardized feeding guideline. Prolonged antibiotic use has been linked with NEC in preterm infants because of alteration of the gut microbiome. In addition, studies have reported significant reductions in NEC associated with the implementation of a standardized feeding guideline.[48]

NEONATAL SEPSIS AND MENINGITIS

CASE 105-5

QUESTION 1: J.E., a 28-week gestation, 0.85-kg male, was born to a mother with prolonged rupture of membranes (>72 hours). The newborn's mother is diagnosed with chorioamnionitis. J.E. had Apgar scores of 3 at 1 minute, 4 at 5 minutes, and 7 at 10 minutes after birth. Mechanical ventilation was instituted, and J.E. was admitted to the NICU. Vital signs on admission were as follows:

HR, 190 beats/minute
Temperature, 96.44 °F (35.8 °C)
BP, 56/33 mm Hg

Blood and urine culture results are pending. Significant laboratory data include the following:

WBC 2400 cells/μL with a differential of 25% segmented neutrophils, 15% bands, 45% lymphocytes, 10% monocytes, 4% eosinophils, and 1% basophils
Platelets, 45,000/μL
CRP, 5 mg/dL

What is the etiology and pathogenesis of neonatal sepsis? What risk factors for sepsis does J.E. have? What clinical signs and laboratory evidence of sepsis are apparent in J.E.?

Bacterial sepsis significantly contributes to neonatal morbidity and mortality. Neonates, especially preterm newborns, are at increased risk for infections and should be considered immunocompromised. The neonate's decreased immune function (eg, immature function of neutrophils, lower amounts of immunoglobulin) also results in a reduced ability to localize infections.[57] Once a tissue site becomes infected, bacteria can spread easily, resulting in disseminated disease. In addition, the lack of opsonic antibodies in preterm infants such as J.E. increases the susceptibility to infections caused by bacteria with polysaccharide capsules (eg, group B streptococcus, *E. coli, Haemophilus influenzae* type B).[58]

The incidence of neonatal sepsis is inversely proportional to BW and GA. The overall rate is about 1 infection per 1000 live births; ranging from 32 cases per 1000 live births for neonates <25 weeks' gestation, 20 cases per 1000 live births for neonates <29 weeks' gestation, 6 cases per 1000 live births for neonates <34 weeks' gestation, 1 case per 1000 for neonates between 34 and 36 weeks' gestation, and 0.5 cases per 1000 for term neonates.[59] Risk factors (as demonstrated in J.E.) include prematurity, low BW, male sex, and predisposing maternal conditions (eg, prolonged rupture of membranes >18 hours, maternal fever, elevated maternal white blood cells [WBC] or left shift, chorioamnionitis, and urinary tract infection).[57,59] Despite treatment, mortality rates for neonatal sepsis can be as high as 30% to 50%, with the highest mortality observed in newborns born before 29 weeks' gestation.[57,59] Meningitis occurs as a complication of bacterial sepsis in 10% to 30% of septic neonates and has a mortality rate of 20% to 60%, depending on the pathogen.[60] Long-term sequelae of meningitis have been reported in

about 40% to 50% of survivors and include hearing loss, blindness, developmental delay, CP, seizure disorders, and hydrocephalus.[58,61]

Common Pathogens

The fetal environment within the amniotic membranes is normally sterile until the onset of labor and delivery. Once the membranes are ruptured, the infant may be at risk for colonization of microorganisms from the maternal genital tract. Many of these organisms do not cause infection in the mother but may be detrimental to the infant. Early-onset neonatal sepsis (sepsis that presents during the first 72 hours of life) usually is caused by organisms acquired from the maternal genital tract. The most common pathogens found in early-onset neonatal sepsis are group B streptococcus (~40%) and *E. coli* (~30%). Other primary pathogens include *Listeria monocytogenes, Enterococcus,* and other gram-negative bacilli (eg, *H. influenzae, Klebsiella pneumoniae*).[57,61]

Late-onset sepsis (sepsis presenting after 3 days' PNA) usually is caused by these primary organisms or by nosocomial pathogens, such as coagulase-negative staphylococci (CONS), particularly *S. epidermidis, S. aureus, Pseudomonas* species, anaerobes, and *Candida* species.[57,61] The presence of IV catheters (umbilical or central) and duration of parenteral hyperalimentation are major risk factors for nosocomial septicemia. Other risk factors include prematurity, low BW, prolonged hospital stay, prior antibiotic use, lipid emulsion, use of H_2-blockers, invasive procedures, GI disease (including NEC), the presence of other indwelling devices (eg, ETTs, ventriculoperitoneal shunts), and nasal CPAP.[57] Late-onset sepsis in infants with central venous access is usually caused by gram-positive organisms, with CONS being the most common pathogen.[57] Clinically, before continuation of antibiotic therapy, it is important to distinguish whether patient isolates of CONS are the result of colonization of the catheters or IV tubing or represent true bacteremia.

Neonatal sepsis may present with nonspecific or subtle signs, especially in VLBW infants. The most common signs are poor feeding, temperature instability, lethargy, or apnea. Other signs of neonatal sepsis include glucose instability (hypoglycemia or hyperglycemia), tachycardia, dyspnea or cyanosis, tachypnea, diarrhea, vomiting, feeding intolerance, abdominal distension, metabolic acidosis, and abnormal WBC.[57,60] Clinical signs and laboratory evidence of neonatal sepsis observed in J.E. include tachycardia (HR, 190 beats/minute), hypothermia (temperature 96.44 °F [35.8 °C]), leukopenia (WBC, 2.4 × 10^3/μL), neutropenia (absolute neutrophil count of 960/μL), a left shift in the differential (ie, an immature-to-total neutrophil ratio [I/T] of 0.38), thrombocytopenia (platelets, 45,000/μL), and an elevated CRP (5 mg/dL). Hypothermia is more common than is fever in neonatal sepsis, especially in preterm newborns. However, if fever is present, it is strongly associated with bacterial infection. Neutropenia, especially with a left shift (as seen in J.E.), can be a sign of WBC depletion from bone marrow owing to overwhelming sepsis. An elevated WBC also can indicate a neonatal infection but may be less specific. The I/T ratio, defined as band forms plus any earlier cells divided by the total neutrophil count (including early cells), has been shown to be useful in diagnosing neonatal sepsis. An I/T ratio of <0.3 is normal.[60] CRP, an acute-phase reactant protein associated with tissue injury in response to an inflammatory process, may also be included as part of a sepsis workup. A CRP level of >1 mg/dL indicates inflammation and possible infection.[60] In infants with bacterial infection, serum CRP levels begin to increase from 6 to 8 hours after the onset of the illness and peak after 2 to 3 days.[62] Therefore, because of the delayed response, the use of CRP for detection of early-onset sepsis is not of great value. Serial CRP levels obtained during 2 to 3 days of illness may aid in the determination of duration of empiric antibiotic therapy. Empiric antibiotic therapy may be discontinued in infants with normal serial CRP levels in the absence of any clinical signs suggestive of sepsis. However, elevated CRP levels can be found in other clinical conditions such as viral infection, ischemic tissue injuries, hemolysis, or chorioamnionitis. Procalcitonin, another acute-

phase reactant, rises more quickly than does CRP in the presence of bacteria, so it may be more useful for early detection. However, there are also limitations to its routine use for the evaluation of neonatal sepsis, including nonspecificity (ie, noninfectious conditions can cause elevation of procalcitonin levels) and a lack of age-specific reference ranges.[62] Therefore, CRP and procalcitonin levels should be used with caution as the sole diagnostic criteria for sepsis or bacteremia. Late signs of neonatal infection include jaundice, hepatosplenomegaly, and petechiae.[60] A bulging fontanel, posturing, or seizures indicate meningitis, although these central nervous system (CNS) signs are not always present when meningitis exists.

Bacterial meningitis should always be considered in infants with neonatal sepsis.[58] The major pathogens causing neonatal sepsis are also the primary pathogens that cause neonatal meningitis.[60] The definitive diagnostic method for bacterial meningitis is lumbar puncture. Lumbar puncture should be performed in infants with a positive blood culture result, abnormal neurologic signs, an elevated WBC or left shift, or the presence of bacteria in the urine.[63] A lumbar puncture is not needed in neonates receiving empiric antibiotics solely because of maternal risk factors.[62] However, it is important to note that a negative blood culture result does not dictate the absence of bacterial meningitis. Approximately 1 of every 4000 live births has culture-proven bacterial meningitis, and 15% to 50% of infants with bacterial meningitis may have a negative blood culture result.[60,62] The cerebrospinal fluid (CSF) should be tested with a Gram stain, cell counts with differential, glucose and protein levels, and bacterial culture. Normal CSF cell counts and protein concentrations are different for neonates compared with older children and adults. For example, the CSF protein concentration in a healthy neonate is about two to three times that of an adult and decreases with age; preterm infants may have higher levels.[58] Neonatal CSF cell counts are also difficult to interpret because values observed with meningitis may overlap with normal neonatal values. The diagnosis of neonatal sepsis is confirmed by isolation of the pathogen from blood, urine, CSF, or other body sites.

Treatment of Sepsis and Meningitis

Case 105-5, Question 2: What antibiotic regimen should be prescribed for J.E.?

Empiric treatment with appropriate IV antibiotics must be initiated immediately in J.E. Significant morbidity or fatality would occur if antibiotics were withheld until a diagnosis was confirmed by culture results (in 24–72 hours). This is especially true in patients in whom meningitis is suspected. The initial empiric antibiotic treatment of choice for early-onset neonatal sepsis and meningitis is ampicillin plus an aminoglycoside (**Tables 105-4** and **105-5**).[2,64,65] These antibiotics are used because they (a) are bactericidal against common neonatal pathogens; (b) penetrate into the CNS; (c) are relatively safe; and (d) have proven clinical efficacy. If the culture result is positive for group B streptococcus, ampicillin should be replaced with high-dose penicillin G because of its higher activity against group B streptococcus. If meningitis is highly suspected, gentamicin may be replaced by a third-generation cephalosporin (ie, cefotaxime or ceftazidime) owing to greater CSF penetration compared with aminoglycosides.

Table 105-4
Gentamicin Dosing Guidelines for Neonates and Infants

Age	Extended-Interval Dosing Regimen[a]
PMA <32 weeks	4–5 mg/kg/dose every 36–48 hours
PMA 32–36 weeks	4–5 mg/kg/dose every 36 hours
PMA ≥37 weeks	4–5 mg/kg/dose every 24 hours

PMA, postmenstrual age.

[a]Some institutions empirically adjust dosing interval based on clinical factors that may affect renal drug clearance (eg, birth depression, hypotension requiring vasopressor support, or congenital heart defects resulting in decreased peripheral perfusion).

The use of antibiotics in neonates weighing less than 1200 grams. *Pediatr Infect Dis J.* 1990;9:111–121; Bradley JS, Nelson JD. *Nelson's Pediatric Antimicrobial Therapy*. 26th ed. American Academy of Pediatrics; 2020.

Therefore, ampicillin 85 mg every 8 hours IV plus an aminoglycoside (eg, gentamicin 4.2 mg every 48 hours IV) should be started in J.E. for suspected neonatal sepsis and possible meningitis. Meningitic doses of ampicillin should be used in J.E. until meningitis can be ruled out. Ampicillin is active against group B streptococci, *Enterococcus*, *Listeria*, and some strains of *E. coli.* Aminoglycoside antibiotics (eg, gentamicin or tobramycin) usually

are active against gram-negative bacilli. In addition, aminoglycosides may provide synergy with ampicillin against *Listeria* and group B streptococci.[59,66] Selection of the specific aminoglycoside should be determined by antibiotic resistance patterns within the NICU. Amikacin should be reserved for gram-negative organisms resistant to gentamicin and tobramycin. Aminoglycoside regimens need to be designed to achieve safe and therapeutic serum concentrations and to aim for a peak concentration that is more than eight times greater than the minimum inhibitory concentration (MIC) of the organism being treated.[67] Peak gentamicin and tobramycin serum concentrations of 10 to 12 μg/mL and trough concentrations of <1 μg/mL may be reasonable, depending on the MIC.

Traditionally, aminoglycosides were administered to neonates in multiple daily doses (eg, gentamicin 2.5 mg/kg/dose two or three times a day). This dosing strategy frequently resulted in peak serum concentrations below and trough concentrations above the respective target ranges, especially in preterm neonates. Evolution of the understanding of developmental pharmacokinetics resulted in knowledge that neonates have a larger volume of distribution for water-soluble drugs and a slower renal elimination of aminoglycosides compared to infants, older children, and adults.[68] Thus, many institutions now use higher milligram per kilogram doses of aminoglycosides (eg, gentamicin 4–5 mg/kg) administered at prolonged dosing intervals (every 24, 36, or 48 hours; commonly determined by GA or PMA).[69,70] A Cochrane review concluded that administering higher milligram per kilogram aminoglycoside doses at prolonged intervals to neonates was as effective as multiple daily doses without evidence of increased toxicity. Serum peak and trough concentrations also were more likely to be in the target range.[71]

This dosing strategy (of giving higher milligram per kilogram per doses at prolonged intervals) in neonates is commonly referred to as *extended-interval aminoglycoside dosing*; however, it should not be confused with the adult dosing method of the same name.[68] Extended-interval aminoglycoside dosing (also known in adults as once-daily dosing or single-daily dosing) has been widely used in the adult population. Aminoglycoside antibiotics display concentration-

dependent killing of bacteria. The rationale for the use of extended-interval aminoglycoside dosing include (a) enhancement of bacterial killing by providing a higher peak serum concentration to MIC ratio, (b) provision of a prolonged postantibiotic effect, and (c) minimization of adaptive postexposure microbial resistance by achieving a drug-free period at the end of the dosing interval.[72] Key differences between this approach to aminoglycoside dosing in adults and the use of higher milligram per kilogram doses given at prolonged intervals to neonates include the following: (a) Peak concentrations of ~20 to 25 μg/mL are targeted in adults compared to 8 to 12 μg/mL in neonates, (b) a drug-free period occurs at the end of the dosing interval in adults, whereas acceptably low, but measurable trough concentrations are commonly observed in neonates, and (c) a standardized dosing nomogram allows for interval adjustments based on a single serum concentration (drawn 8–12 hours postdose) in adults; however, routine peak and trough concentration monitoring is recommended for neonates.[68,72,73]

In some nurseries, a third-generation cephalosporin (eg, cefotaxime or ceftazidime), instead of an aminoglycoside, is added to ampicillin for initial empiric treatment of early-onset neonatal sepsis and meningitis.[60,67] The spectrum of activity of these third-generation cephalosporins includes many gram-negative organisms and group B streptococci. Ceftriaxone should be avoided in neonates with hyperbilirubinemia owing to bilirubin displacement from albumin-binding sites. Ceftriaxone has also been associated with sludging in the gallbladder and cholestasis.[2,67] The resultant increase in serum-free bilirubin concentrations and decrease in bilirubin elimination can place the neonate at risk for kernicterus. In addition, calcium–ceftriaxone precipitates have been found in the lungs and kidneys of neonates when ceftriaxone was administered with calcium-containing solutions. Several fatalities have been reported; ceftriaxone should not be administered within 48 hours of calcium-containing solutions or products.[67] Hence, cefotaxime or ceftazidime is the preferred cephalosporin for neonatal use.

The third-generation cephalosporins have advantages over the aminoglycosides, including better CNS penetration, the elimination of

serum concentration measurements, and less nephrotoxicity. However, these cephalosporins do not significantly improve clinical or microbiologic end points compared with the standard ampicillin and gentamicin regimen. In fact, overuse of cefotaxime during the first few days of life has been associated with an increased risk of death compared with the use of gentamicin.[67] Furthermore, extensive use of the third-generation cephalosporins in NICUs may lead to rapid emergence of resistant gram-negative bacilli (eg, *Enterobacter cloacae*, *Pseudomonas aeruginosa,* and *Serratia* species) and vancomycin resistance in enterococci. Also, prolonged treatment has been associated with an increased risk of neonatal candidiasis.[67] In contrast, only rare cases of gentamicin resistance have been reported.[59,66] Thus, combinations such as ampicillin and cefotaxime or ceftazidime should be reserved for the following situations: (a) NICUs in which aminoglycoside resistance to gram-negative enteric bacilli is of concern, (b) NICUs in which serum concentrations of aminoglycosides cannot be measured, and (c) specific neonates in whom aminoglycoside therapy could be of concern (eg, neonates with known renal failure).

Therapy for late-onset sepsis or meningitis is directed toward nosocomial pathogens plus the primary pathogens of early-onset infection. Selection of initial antibiotic therapy should consider the specific NICU's nosocomial pathogen and antibiotic resistance patterns, as well as the neonate's risk factors, clinical condition, and previous antibiotic therapy. CONS is now the most common pathogen of late-onset neonatal nosocomial septicemia.[74] Because of the high incidence of methicillin-resistant CONS, vancomycin has been used as the drug of choice for empiric therapy for suspected late-onset neonatal sepsis. However, widespread use of vancomycin has led to the emergence of vancomycin-resistant *Enterococcus* and *S. aureus.* Therefore, the routine use of vancomycin as empiric therapy for nosocomial neonatal sepsis should be discouraged. The highly selective use of vancomycin for neonatal CONS septicemia results in low morbidity and mortality, while significantly reducing vancomycin use. Guidelines for the selective use of vancomycin should be tailored according to individual NICU's nosocomial

pathogens, susceptibility patterns, and patient risk factors, clinical condition, and antibiotic history. Therefore, if J.E. had a central venous catheter and presented with a late-onset sepsis, initial antibiotic therapy should include an aminoglycoside (for gram-negative coverage) plus either antistaphylococcal penicillin (eg, nafcillin, methicillin) or vancomycin (for activity against *S. aureus* and *S. epidermidis*). Vancomycin is used in place of the antistaphylococcal penicillin in neonatal units with methicillin-resistant *S. aureus* and for selective use to cover *S. epidermidis* (a CONS) as outlined.[74]

For systemic fungal infections, amphotericin B is considered the initial treatment of choice.[57,75] *Candida* species are the third most common organism causing neonatal sepsis, so prophylactic fluconazole may be used to prevent *Candida* colonization and infection. Infants weighing <1 kg benefited most from prophylactic fluconazole. Despite potential benefits, routine use of prophylactic fluconazole is not recommended and should be reserved for those units with a high incidence of fungal infections.[75] Because uncommon organisms are not suspected in J.E., the regimen of ampicillin 85 mg IV every 8 hours plus gentamicin 4.2 mg IV every 48 hours is appropriate.

Once a pathogen is isolated, the antimicrobial susceptibilities should be evaluated, and the drug therapy modified appropriately. Blood, CSF, or urine cultures should be repeated to document bacterial sterilization after 24 to 48 hours of appropriate therapy. J.E. should be evaluated carefully for the development of serious bacterial complications such as meningitis, osteomyelitis, abscess formation, or endocarditis.

DURATION OF THERAPY

As long as there is no evidence of meningitis or other focal infection (eg, abscess formation), the duration of therapy for most systemic bacterial infections is 7 to 10 days (or ~5–7 days after significant clinical improvement). Antibiotic therapy may need to be continued for 14 to 21 days if the neonate’s clinical response is slow or if

multiple organ systems are involved.[61] If culture results are negative at 48 hours and the infant does not have any clinical or laboratory signs of sepsis, antibiotics can be discontinued. In neonates presenting with signs of severe infection followed by improvement after initiation of antibiotics, therapy may be continued despite negative culture results.[66]

If CSF culture results are positive, repeat CSF cultures should be obtained daily or every other day in J.E. to document when the CSF becomes sterilized. The duration of therapy for neonatal meningitis depends on the clinical response and duration of positive CSF cultures after therapy is initiated. Appropriate antibiotics should be continued for a minimum of 14 days after the CSF is sterilized. This is equivalent to the duration of antibiotic therapy for a minimum of 21 days for gram-negative organisms and at least 14 days for gram-positive pathogens.[57,60] As a general rule, it takes longer to sterilize the CSF of neonates infected by gram-negative enteric bacilli (72 hours) than those infected by gram-positive bacteria (36–48 hours).[60]

CONGENITAL INFECTIONS

Torch Titers

CASE 105-6

Question 1: S.Y., a 2-kg female, was born at 34 weeks' GA by vaginal delivery. S.Y.'s birth was complicated by prolonged rupture of membranes (>72 hours) and fetal distress requiring a fetal scalp monitor. On physical examination, S.Y. is an extremely irritable newborn with an RR of 60 breaths/minute. Several vesicular skin lesions located on the scalp and around the eyes are noted. Conjunctivitis is also present. S.Y. is placed on supplemental oxygen, and ABGs are obtained. Blood, CSF, and urine were cultured for bacteria and fungus, and S.Y. was started on ampicillin 200 mg IV every 8 hours and gentamicin 9 mg IV every 36 hours to rule out sepsis. Antimicrobial therapy will not be altered until culture results are available.

What other tests and information are needed for S.Y. at this time?

Certain bacteria, viruses, and protozoa can cause fetal infections that may result in fetal death, congenital anomalies, serious CNS sequelae, intrauterine growth retardation, or preterm birth.[76] The primary organisms that cause these infections can be remembered by the acronym, TORCH: toxoplasmosis; other (ie, syphilis, gonorrhea, hepatitis B, listeria); rubella; cytomegalovirus; and herpes simplex. Because of the potential severity of these diseases, newborns who display any signs of infection (eg, irritability, fever, thrombocytopenia, hepatosplenomegaly) need to be evaluated for these intrauterine and perinatally acquired infections. A complete infectious disease workup should include specific antibody titer measurements or polymerase chain reaction (PCR) to the suspected organisms.[76]

Primary clinical manifestations and treatment regimen for selected congenital infections are listed in **Table 105-6**.[2,61,76,77] The clinical signs of these infections may overlap, and concurrent infection with two or more microorganisms is possible. The detection of congenital infections often is difficult because many neonates are asymptomatic at birth. Therefore, prenatal maternal screening and accurate evaluation of maternal history for risk factors are very important. Other organisms that can cause congenitally acquired infections include human immunodeficiency virus, human parvovirus, varicella-zoster virus, and measles virus.[76]

Table 105-6
Selected Congenital and Perinatal Infections in the Neonate

Organism	Primary Clinical Manifestations	Treatment of Proven or Highly Probable Disease[a]
Herpes simplex	Cutaneous vesicles, keratoconjunctivitis, microcephaly, CNS infection, hepatitis, pneumonitis, prematurity, respiratory distress, sepsis, convulsion, chorioretinitis	Acyclovir *Ocular involvement:* Add topical therapy: 1%–2% trifluridine, or 0.15% ganciclovir

Organism	Primary Clinical Manifestations	Treatment of Proven or Highly Probable Disease[a]
Toxoplasmosis	Chorioretinitis, ventriculomegaly, microcephaly, hydrocephaly, intracranial calcifications, ascites, hepatosplenomegaly, lymphadenopathy, jaundice, anemia, mental retardation	Sulfadiazine *and* pyrimethamine *and* leucovorin (folinic acid)
Treponema pallidum	*Early:* Osteochondritis, periostitis, hepatosplenomegaly, skin rash (maculopapular or vesiculobullous), rhinitis, meningitis, IUGR, jaundice, hepatitis, anemia, thrombocytopenia, chorioretinitis	Penicillin G
	Late: Hutchinson triad (interstitial keratitis, VIII nerve deafness, Hutchinson teeth), mental retardation, hydrocephalus, saddle nose, mulberry molars	
Hepatitis B	Prematurity; usually asymptomatic; long-term effects include chronic hepatitis, cirrhosis, liver failure, hepatocellular carcinoma	*Perinatal exposure (maternal HbsAg positive):* HBIG and hepatitis B vaccine
Rubella	*Early:* IUGR, retinopathy, hypotonia, hepatosplenomegaly, thrombocytopenic purpura, bone lesions, cardiac effects *Late:* Hearing loss, mental retardation, diabetes *Rare:* Myocarditis, glaucoma, microcephaly, hepatitis, anemia	Supportive care

Organism	Primary Clinical Manifestations	Treatment of Proven or Highly Probable Disease[a]
Cytomegalovirus	Petechiae, hepatosplenomegaly, jaundice, prematurity, IUGR, increased liver enzymes, hyperbilirubinemia, anemia, thrombocytopenia, interstitial pneumonitis, microcephaly, chorioretinitis, intracranial calcifications *Late:* Hearing loss, mental retardation, learning and motor abnormalities, visual disturbances	Valganciclovir Ganciclovir
Neisseria gonorrhoeae	Ophthalmia neonatorum, scalp abscess, sepsis, arthritis, meningitis, endocarditis	Ceftriaxone Use cefotaxime/ceftazidime if hyperbilirubinemic

CNS, central nervous system; HBIG, hepatitis B immune globulin; HbsAg, hepatitis B surface antigen; IUGR, intrauterine growth retardation.

[a]See references 2 and 61 for dosing and recommended treatment duration.

When congenital infections are suspected, appropriate diagnostic tests for each suspected organism should be performed. Viral cultures of the urine, oropharynx, nasopharynx, stool, and conjunctiva, and a complete maternal history along with the results of recent maternal vaginal cultures also should be obtained.[76] Measurements of immunoglobulin M levels specific for each possible organism under consideration are also recommended. S.Y. has signs of a congenital infection (respiratory distress, skin rash, and conjunctivitis). Because of the nature of S.Y.'s skin rash (ie,

vesicular), infection with the herpes simplex virus (HSV) should be highly suspected. Skin vesicles, conjunctiva, oropharynx, nasopharynx, rectum, urine, and CSF should be cultured for HSV and other organisms known to cause congenital infections. Rapid diagnostic testing using tissue scrapings from vesicles and fluorescein-conjugated monoclonal HSV antibody can also be performed. Other appropriate tests for the diagnosis and workup of suspected congenital infections should also be performed (eg, liver enzymes, prothrombin time, partial thromboplastin time, electroencephalogram [EEG], computed tomography scan, or magnetic resonance imaging).[76]

APNEA OF PREMATURITY

Apnea in neonates is a life-threatening condition that occurs more frequently in premature newborns and newborns of lower BWs. Nearly all infants born before 29 weeks' gestation will have apnea. The incidence declines with increasing GA from 85% of those born at 30 weeks' gestation to 20% of those born at 34 weeks' gestation.[78] Clinically significant apnea is generally defined as cessation of breathing for at least 20 seconds, or less, if accompanied by bradycardia (HR <100 beats/minute), significant hypoxemia, cyanosis, or pallor.[78]

In neonates, apnea may be caused by a severe underlying illness (eg, infection, metabolic disorders, seizures, intracranial pathology), drugs, or prematurity itself. Appropriate patient history, physical examination, and laboratory tests must be evaluated to rule out other causes of apnea before the diagnosis of apnea of prematurity can be made.[79] It is especially important to rule out sepsis before apnea of prematurity is presumed. If an etiology other than prematurity is identified, therapy would be directed toward that specific cause. For example, antibiotics are used to treat neonatal sepsis with secondary apnea.

Apnea of prematurity is classified into three types: central (ie, no respiratory effort), obstructive, and mixed (ie, both central and obstructive). Mixed apnea accounts for the majority (50%–75%) of apnea of prematurity episodes.[79] Treatment of apnea of prematurity includes the use of supplemental oxygen, gentle tactile stimulation, environmental temperature control, methylxanthines, nasal CPAP, and positive-pressure ventilation.

CASE 105-7

QUESTION 1: S.M., a premature male newborn of 29 weeks' GA, had a BW of 0.99 kg. On day 2 of life, he experienced seven episodes of apnea followed by bradycardia with HR as low as 85 beats/minute. These episodes lasted 20 to 30 seconds and required administration of oxygen and tactile stimulation. Three prolonged episodes required bag-and-mask ventilation. Between apneic spells, the newborn seemed well; physical examination and laboratory test results were normal for GA. Appropriate cultures were drawn for a septic workup, and ampicillin and gentamicin were initiated.

How should S.M.'s apnea be managed?

Methylxanthines are widely accepted as the initial pharmacologic approach for the treatment of idiopathic apnea of prematurity, with caffeine being preferred over theophylline or aminophylline.[78,79] These agents decrease apneic episodes via both central and peripheral effects. Methylxanthines stimulate the medullary respiratory center and increase receptor responsiveness to carbon dioxide. This results in an increase in respiratory drive and minute ventilation. Central stimulatory effects may be mediated by adenosine receptor blockade. Adenosine is a known inhibitor of respiration, and both theophylline and caffeine competitively inhibit adenosine at the receptor level.[78] Peripherally, methylxanthines increase diaphragmatic contractility, decrease diaphragmatic fatigue, and improve respiratory muscle contraction. In addition, methylxanthines increase catecholamine release and metabolic rate.[79] This may improve cardiac output and oxygenation, lessen hypoxic episodes, and decrease apneic spells.

Methylxanthine therapy generally is initiated for apnea of prematurity when apneic episodes are frequent, prolonged for ≥20 seconds, are accompanied by significant bradycardia or cyanosis, or are not controlled by nonpharmacologic means. S.M. has had prolonged apneas with bradycardia that have required supplemental oxygenation. Initiation of a methylxanthine would be appropriate at this point.

CASE 105-7, QUESTION 2: On rounds, the NICU medical team asks you how caffeine compares with theophylline with regard to its pharmacokinetics, efficacy, and toxicity? What treatment and dose should be selected for S.M.? How do you reply to the team?

The plasma clearance of caffeine is considerably lower, and the half-life is extremely prolonged in the premature newborn (72–96 hours).[2] The low clearance is a reflection of the decreased neonatal hepatic metabolism and a resultant dependence of elimination on the slow urinary excretion.[80] As a result, caffeine can be dosed once daily (every 24 hours) in the neonate. The half-life of caffeine decreases with increasing PMA,[81] and plasma clearance reaches adult levels after 3 to 4.5 months of life.[82] As a result of the maturational changes, doses usually need to be adjusted after 38 weeks' PMA; however, most infants no longer require treatment of apnea beyond 34 to 36 weeks' PMA.

Protein binding of theophylline is decreased in term newborns compared with adults.[83] The decreased protein binding along with an increased tissue distribution results in a larger volume of distribution of theophylline in neonates. This larger volume of distribution results in larger loading-dose requirements to attain similar serum concentrations. Similar to caffeine, theophylline clearance in preterm newborns is much slower than that observed in young children ages 1 to 4 years.[83] As a result, smaller theophylline maintenance doses are required in neonates. Theophylline clearance and, therefore, maintenance doses increase with increasing PMA.[84]

In adults, theophylline is eliminated primarily via hepatic metabolism.[85,86] In contrast, the primary route of theophylline

elimination in neonates is renal excretion of unchanged drug (55%).[84] Hepatic metabolism of theophylline (especially *N*-demethylation) is decreased in the neonate. As in adults, theophylline is methylated to caffeine in the neonate. The neonate's decreased demethylation pathway, however, results in a decrease in caffeine elimination and significant serum caffeine accumulation. On average, serum caffeine concentrations can be 40% of the serum theophylline concentration.[84] The theophylline-derived caffeine may contribute to the pharmacologic and toxic effects seen in neonates receiving theophylline.

Comparative studies have found similar efficacy for theophylline and caffeine in the control of apnea of prematurity. Caffeine, however, has several advantages over theophylline, including a wider therapeutic index. Adverse effects such as tachycardia, CNS excitation, and feeding intolerance are reported more frequently with theophylline than with caffeine. Because the half-life is prolonged and dosing requirements do not change quickly with time, caffeine serum concentrations do not need to be routinely monitored. The great majority of preterm neonates achieve caffeine plasma concentrations within the therapeutic range (5–20 μg/mL) if they receive standard doses.[82] Caffeine serum concentrations may be obtained in select neonates (eg, patients with clinical signs of toxicity or with intractable apnea). Loading doses of 20 mg/kg caffeine citrate (10 mg/kg caffeine base), followed 24 hours later by maintenance doses of 5 to 10 mg/kg caffeine citrate (2.5–5 mg/kg caffeine base) given daily, are recommended. Caffeine can be given by syringe infusion pump or orally.[2] Because of the longer half-life, infants receiving caffeine must be monitored for a longer time (eg, for 7–10 days) for adverse effects if toxicities occur and for apnea recurrence once the medication is discontinued. It is important to remember that another IV caffeine product is marketed in the United States as sodium benzoate salt. Benzoic acid has been associated with the gasping syndrome and may also displace bilirubin from albumin-binding sites.[2] Because of these toxicities, the caffeine sodium benzoate product should not be used in neonates.

The short- and long-term safety and efficacy of caffeine to treat apnea of prematurity in VLBW infants were studied in a large, randomized, placebo-controlled trial.[87,88] Caffeine significantly decreased the frequency of BPD.[87] Infants who received caffeine were able to have positive airway pressure discontinued 1 week sooner than did those receiving placebo. Although caffeine reduced weight gain, the effect was only temporary (during the first 3 weeks of therapy). In a follow-up study at 18 to 21 months' corrected age, caffeine significantly improved the rates of survival without neurodevelopmental disability (eg, CP, cognitive delay).[88] These benefits were greater if caffeine was started within 2 days of birth, but were not sustained at 5-year follow-up.[89,90]

The generally accepted therapeutic trough range of theophylline for apnea of prematurity is 6 to 12 μg/mL. This range is lower than that which is normally accepted for the treatment of asthma (5–15 μg/mL) for several reasons: (a) The higher free fraction of theophylline found in neonates results in a higher free concentration at any given total concentration; (b) there is a significant accumulation of the unmeasured active metabolite, caffeine; and (c) a different mechanism of action for theophylline is being exploited for apnea (ie, central stimulation vs bronchodilation for asthma). Aminophylline IV loading doses and maintenance doses of aminophylline and theophylline can be found in appropriate pediatric references.[2] However, a large variation in serum theophylline concentrations has been observed with some dosing regimens.[91] Concomitant drug therapy and disease states (eg, hepatic or renal dysfunction) should also be taken into consideration when selecting initial theophylline doses.

Serum theophylline concentrations should be monitored 72 hours after initiation of therapy or after a change in dosage. Serum concentrations of theophylline should also be measured if the infant experiences an increase in the number of apneic episodes, signs or symptoms of toxicity, or a significant increase in weight. In asymptomatic neonates, once steady-state levels are obtained, theophylline concentrations may be monitored every 2 weeks.

Because of the many advantages of caffeine over theophylline, S.M. should be given 20 mg of caffeine citrate (10 mg caffeine base) as an IV loading dose for 30 minutes. Maintenance doses of 5 mg of caffeine citrate (2.5 mg caffeine base) every 24 hours should be started 24 hours after the loading dose.

CASE 105-7, QUESTION 3: The NICU medical resident asks you to outline a pharmacotherapeutic monitoring plan for S.M. that includes monitoring parameters for efficacy and toxicity and duration of therapy. What would you tell her?

The goal of methylxanthine therapy for S.M. is to decrease the number of episodes of apnea and bradycardia. Continuous monitoring of HR and RR is required for proper evaluation. The time, duration, and severity of episodes, activity of the infant, and any necessary intervention performed should be documented. Relationships between the apneic episodes and the feeding schedule and volume of feeds, as well as the dosing schedule, should be examined. Apnea of prematurity usually resolves by 34 to 36 weeks' PMA; however, it may persist in some infants up to or beyond 40 weeks' PMA.[78] Methylxanthine therapy usually is discontinued at 34 to 36 weeks' PMA provided that the infant has not been having apneic spells. Infants requiring therapy for longer periods may be discharged home on methylxanthines with apnea monitors; however, this occurs very rarely.

Methylxanthine toxicities noted in neonates include tachycardia, agitation, irritability, hyperglycemia, feeding intolerance, gastroesophageal reflux, and emesis or occasional spitting up of food. Tachycardia is the most common toxicity and usually responds to a downward adjustment of the dose. Tachycardia may persist for 1 to 3 days after dosage reductions owing to the decreased elimination of caffeine. Seizures have also been reported with accidental overdoses. Methylxanthine toxicity can be minimized with careful dosing and appropriate monitoring.

NEONATAL SEIZURES

CASE 105-8

QUESTION 1: F.H., a term female newborn (weight 3.5 kg), has a history of birth depression due to placenta abruptia. Apgar scores were 0, 1, 4, and 7 at 1, 5, 10, and 15 minutes, respectively. Maternal history is negative for drug abuse. Twenty-four hours after birth, F.H. begins to have rhythmic clonic twitching of the right hand, repetitive chewing movements, fluttering of the eyelids, and occasional pendulum-like movements of the extremities that resemble swimming motions.

How should F.H.'s seizure activity be evaluated?

Seizure activity may be difficult to recognize in the term or premature neonate. Because of the immaturity of the cortex, neonatal seizures rarely are generalized tonic–clonic events, but can be clonic (focal or multifocal), tonic (focal or generalized), myoclonic (focal, multifocal, or generalized), or subtle in nature.[92]

Subtle seizures include activities such as abnormal oral-buccal-lingual movements; ocular movements; swimming, pedaling, or stepping movements; and, occasionally, apnea. In addition, autonomic nervous system signs such as changes in HR, BP, respirations, skin color, oxygenation, salivation, or pupil size may occur.[92] Clinical neonatal seizures may or may not be associated with EEG changes. In addition, electrographic seizure activity may occur in neonates without clinical manifestations (ie, subclinical seizures).

Neonatal seizure activity is a common manifestation of a life-threatening underlying acute neurologic disorder. The most common underlying etiologies are hypoxic-ischemic encephalopathy (HIE) accounting for 40% to 50% of all neonatal seizures followed by arterial stroke, and intracranial hemorrhage. Other etiologies include intracranial infection, cerebral dysgenesis, metabolic or electrolyte imbalances (eg, alterations in glucose, calcium, magnesium, or sodium), drug-related causes (eg, withdrawal after maternal drug use or adverse effects from drugs administered before, during, or

after delivery), genetic disorders, and neonatal epileptic syndromes.[92] The onset of neonatal seizures is dependent on the etiology. Those with HIE, stroke, and metabolic disturbances will develop seizures within the first 3 days of life, whereas those with intracranial hemorrhage or infection can develop seizures at any time. Definitive treatment is directed toward specific identified etiologies. The acute evaluation of neonatal seizures includes an assessment of the infant's airway, breathing, and circulation and a review of the infant's history, physical examination, and laboratory studies. Every neonate with seizure activity should have a bedside determination of glucose; laboratory determinations of serum electrolytes, including sodium, BUN, glucose, calcium, and magnesium; blood gases; bilirubin; and an infectious disease workup, including complete blood cell count with platelets, CRP level, blood culture, urine culture, lumbar puncture with CSF analysis (cell count, protein, glucose), and CSF culture.[92] Because many seizures have subtle manifestations such as ocular or orolingual movements, the clinical diagnosis of seizures can be difficult. An EEG, preferably continuous EEG, can help determine whether clinical seizures are correlated with electrical seizures, thus necessitating anticonvulsant therapy. Treatment with antiepileptic drugs can be initiated while laboratory test results are pending, and electrolyte imbalances have been corrected.

If these tests do not reveal any abnormalities, a metabolic disease workup (eg, serum ammonia, lactate, and pyruvate; serum and urine amino and organic acids) and screening of blood and urine for drugs can be performed.[92,93] Intrauterine infections associated with congenital neurologic abnormalities and seizures can be identified by obtainment of TORCH titers or PCR for specific viruses (eg, CMV, HSV). Cranial ultrasounds, computed tomography scans, and magnetic resonance images may be obtained to identify infarcts, hemorrhages, calcifications, or cerebral malformations that may cause seizure activity.[92]

Case 105-8, Question 2: F.H. is found to have adequate ventilation and circulation. An IV line is established; blood and CSF cultures and serum

chemistries, including calcium and magnesium, are obtained. A bedside blood glucose (BG) determination reveals a BG of 20 mg/dL. What is your assessment and recommendation at this time?

Hypoglycemia seems to be the cause of F.H.'s seizure activity. HIE secondary to birth depression, however, is the most common cause of neonatal seizures and can be associated with metabolic abnormalities such as hypoglycemia, hypocalcemia, and hyponatremia (owing to inappropriate secretion of antidiuretic hormone).[92] The definition of clinically significant hypoglycemia in neonates remains controversial because normal BG depends on a variety of factors, including GA, BW, feeding status, body stores, and other disease states. The definition of neonatal hypoglycemia varies between organizations. The AAP defines it as a BG < 45 mg/dL during the first 48 hours of life and <60 mg/dL after 48 hours of age compared to <50 mg/dL and 60 mg/dL, respectively, as defined by the Pediatric Endocrine Society.[94] F.H. should receive an IV bolus dose of 7 mL (2 mL/kg) of dextrose 10% (0.2 g/kg) given in 2 to 3 minutes, followed by a continuous infusion of dextrose 10% at an initial dose of 6 to 8 mg/kg/minute (0.5 g/kg/hours).[92] Serum glucose levels should be monitored, and the dextrose infusion should be titrated as needed. If hypoglycemia persists, possible causes such as islet tumor of the pancreas, adrenal insufficiency, and inborn errors of metabolism should be investigated. Corticosteroids, glucagon, diazoxide, and octreotide have been used to treat persistent hypoglycemia.[95]

Treatment of Hypocalcemia and Hypomagnesemia

Case 105-8, Question 3: F.H. receives 7 mL (0.7 g) of 10% dextrose solution IV, and a continuous IV infusion of glucose at 8 mg/kg/minute is initiated. A repeat bedside BG determination reveals a BG of 80 mg/dL, but F.H. continues to have seizure activity. F.H.'s laboratory results come back with the following results:

Sodium, 137 mEq/L
Potassium, 4.3 mEq/L
CO_2, 22 mEq/L
Chloride, 104 mEq/L
BUN, 7 mg/dL
SCr, 0.7 mg/dL
Glucose, 25 mg/dL
Magnesium, 1.0 mEq/L
Calcium, 6.5 mg/dL (1.62 mmol/L)

What should be done next to control F.H.'s seizures?

F.H. also has hypocalcemia and hypomagnesemia, both of which may cause seizure activity. Neonatal hypocalcemia is defined as a serum calcium <7.5 mg/dL (<1.87 mmol/L) in preterm and <8 mg/dL (<2 mmol/L) in term infants or an ionized serum calcium <3 mg/dL (<0.75 mmol/L).[93] Hypomagnesemia (defined as serum magnesium <1.5 mEq/L) is rare but may coexist with hypocalcemia. Hypomagnesemia should be suspected when hypocalcemia cannot be corrected despite large doses of calcium.

F.H. should receive calcium gluconate 700 mg (200 mg/kg) given slowly IV (peripheral concentration diluted to 50 mg/mL, central concentration, 100 mg/mL) and magnesium sulfate 25 to 50 mg/kg/dose (0.2–0.4 mEq/kg/dose) IV as a dilute solution (maximal concentration, 100 mg/mL) administered for 2 to 4 hours.[2,92,93] Doses of calcium gluconate and magnesium sulfate may be repeated based on serum determinations. If IV calcium is administered too quickly, vasodilation, hypotension, bradycardia, cardiac arrhythmias, and cardiac arrest may occur. Calcium gluconate may be administered slowly IV at a maximal rate of 50 mg/minute while monitoring HR, BP, and electrocardiogram.[2] The IV site should be closely monitored for signs of infiltration because extravasation may result in severe dermal necrosis.

Treatment With Antiepileptic Drugs

Case 105-8, Question 4: Despite normalization of her laboratory tests, F.H. continues to have seizure activity. Phenobarbital 35 mg IV push for 1 minute is administered. Ten minutes later, F.H. continues to have intermittent seizure activity. What pharmacotherapeutic plan could control F.H.'s seizure activity?

Phenobarbital remains the first-line antiepileptic drug of choice for neonatal seizures, despite suboptimal efficacy, neurotoxicity, and altered pharmacodynamics effects in neonates.[92,93] Because of the large volume of distribution of phenobarbital in neonates (0.8–1 L/kg), large initial loading doses of 20 mg/kg are required to produce therapeutic serum concentrations.[2,92,96] Because F.H. received only a 10-mg/kg dose (35 mg) of phenobarbital, an additional 10 mg/kg should be given now. Phenobarbital should be administered IV at a rate of ≤1 mg/kg/minute,[2] so a 35-mg dose should be given for at least 10 minutes, not in 1 minute. Rapid administration of phenobarbital may cause respiratory depression, apnea, or hypotension. If F.H. continues to have seizure activity after a total phenobarbital loading dose of 20 mg/kg, additional 5- to 10-mg/kg loading doses may be given every 15 to 20 minutes as needed up to a total cumulative loading dose of 40 mg/kg. Despite it being the drug of choice, cessation of seizures occurs in only 40% of the infants after a loading dose of 20 mg/kg but increases to 70% after a cumulative dose of 40 mg/kg is administered.[92] Ventilatory support may be required when using these higher doses, and serum phenobarbital concentrations should be monitored. Phenobarbital's therapeutic effect of controlling neonatal seizures plateaus at serum concentrations of 40 µg/mL; adverse effects increase at higher serum concentrations.

Currently, there is no consensus regarding a second-line drug, which varies between phenytoin, levetiracetam, benzodiazepines, and lidocaine.[92] If seizure activity is not controlled in F.H. (despite optimal phenobarbital loading doses), phenytoin may be added to phenobarbital at a loading dose of 70 mg (20 mg/kg) should be administered IV at a rate of 0.5 to ≤1 mg/kg/minute.[2,92,93] Rapid IV administration of phenytoin may cause cardiac arrhythmias, bradycardia, or hypotension. Phenytoin may cause severe damage

to tissues if extravasation occurs. Therefore, BP, HR, electrocardiogram, and the IV site of infusion should be monitored. Furthermore, phenytoin should be diluted with normal saline because it is insoluble in aqueous solutions and precipitates in dextrose IV solutions. Fosphenytoin, the diphosphate ester salt of phenytoin, is available in the United States for IV and IM use in adults and is dosed in phenytoin equivalents (PE).[2,92] Fosphenytoin is a water-soluble prodrug of phenytoin that undergoes conversion by plasma and tissue esterases to phenytoin, phosphate, and formaldehyde. Because of its greater water solubility, the IV preparation does not contain propylene glycol, and thus fosphenytoin may have fewer cardiovascular adverse effects associated with IV administration and can be infused at a faster rate (3 mg PE/kg/minute). In addition, it can be safely administered via IM and may cause less dermal necrosis if extravasated. Furthermore, it is compatible with more diluents such as normal saline and dextrose solutions. Unfortunately, appropriate clinical studies of fosphenytoin in neonates have not yet been conducted. Unanswered concerns about the neonatal handling of formaldehyde also exist. Despite the lack of neonatal studies, most clinicians prefer to use fosphenytoin instead of phenytoin because of the aforementioned advantages.

Levetiracetam is a newer antiepileptic drug that has been shown to be efficacious in treating various seizures in children and adults. Experimental studies have reported levetiracetam to be neuroprotective when used in infants with seizures not due to HIE.[92] Recently, the off-label use of levetiracetam as second-line treatment for neonatal seizures, before phenytoin, has been increasing among clinicians mainly due to its favorable safety and pharmacokinetic profiles.[92,97] Levetiracetam has been shown to be efficacious in neonatal seizures in 30% to 100% of patients; however, these were mostly case reports and case series.[92,97,98] The optimal neonatal dose of levetiracetam has not been established. Given that levetiracetam is primarily excreted via the kidney (66% of a dose is excreted as an unchanged drug in the urine) and that the renal function of neonates is decreased compared with that of older infants, one would expect a lower clearance and the use of lower

levetiracetam doses in neonates. However, neonatal pharmacokinetic studies have identified a larger volume of distribution per kilogram (compared to children) and a more rapid clearance than expected based on immature renal function.[98,99] A significant increase in levetiracetam clearance also occurred during the first week of life, reaching the clearance seen in children. These findings indicate that in neonates, larger loading doses and maintenance doses, with an adjustment of maintenance doses after the first 7 days of life, would be required. However, in preterm infants, the elimination half-life may be prolonged because of their immature renal function.[98,99] In clinical practice, an IV loading dose of 30 to 60 mg/kg (up to 80–100 mg/kg) has been used. Serum concentrations of levetiracetam do not correlate with efficacy and, therefore, are not required.[92,98,99]

Phenobarbital has many acute (ie, hypotension, respiratory depression) and long-term (ie, cognitive impairments) adverse effects. Owing to the favorable safety and PK profile of levetiracetam, several studies have been conducted to compare levetiracetam to phenobarbital as the first-line agent for neonatal seizures. Currently, two randomized controlled trials evaluating levetiracetam to phenobarbital as first-line agent for the treatment of neonatal seizures demonstrated conflicting results.[98,100] Levetiracetam 20 to 40 mg/kg was found to be significantly more effective in seizure control compared to phenobarbital 20 to 30 mg/kg in the treatment of neonatal seizures in term and preterm infants (86% vs 62%). However, a recent study reported a lower efficacy rate with levetiracetam of 40 to 60 mg/kg (28%) compared to 20 to 40 mg/kg of phenobarbital (80%).[98] Adverse effects including hypotension and respiratory depression were more common with the phenobarbital group in both studies. The differences between these studies were that in the former study, both term and preterm were included and seizure activity was not assessed using video EEG. These may explain why levetiracetam may be more effective than is phenobarbital. Other differences included the lack of therapeutic hypothermia for infants with HIE, a high proportion of infants with seizures due to sepsis/meningitis, and a lower levetiracetam dose

administered in the former study.[98] Video EEG is often needed to confirm cessation of seizures because most neonatal seizures are symptomatic and self-resolving. Therapeutic hypothermia may have some effect on the seizure control. Furthermore, a higher efficacy rate was noted when the levetiracetam dose was increased from 40 mg/kg to 60 mg/kg in the latter study as well as in previous PK studies. These differences in study design may have impacted the overall efficacy of levetiracetam and phenobarbital for the treatment of neonatal seizures. At this time, it appears that levetiracetam should not be used as first-line therapy for the treatment of neonatal seizures owing to a lack of evidence. Studies comparing long-term neurodevelopmental outcomes of levetiracetam and phenobarbital are needed to evaluate whether a less effective drug in achieving cessation of seizure but better neurodevelopmental outcome through its neuroprotective properties may be preferred.

Lorazepam IV (0.05–0.1 mg/kg) can be used to treat F.H.'s seizures if they are unresponsive to phenobarbital and phenytoin.[2,92,93] Lorazepam is preferred over diazepam owing to its longer duration of effect and fewer pharmaceutical adjuvants. Lorazepam (especially in combination with phenobarbital) may cause respiratory and CNS depression. RR, BP, and HR should be monitored. Doses should be diluted with an equal volume of 5% dextrose in water, normal saline, or sterile water for injection before IV use and administered slowly for 2 to 5 minutes.[2] If seizure activity continues in F.H., continuous IV infusion of midazolam can be administered for the treatment of refractory neonatal seizures.

Continuous lidocaine infusion, carbamazepine, clonazepam, lamotrigine, topiramate, valproic acid, and lacosamide have also been used to treat refractory neonatal seizures in limited number of patients.[97,101] Because of the risk of cardiac arrhythmia associated with lidocaine, its use in the management of refractory neonatal seizures is limited.[101] Owing to the high risk of valproic acid–associated hepatotoxicity for patients younger than age 2 years, this drug is not a preferred agent for use in neonates.[2] IV pyridoxine (50–100 mg) should be considered when seizure activity persists. Pyridoxine is a cofactor required for the synthesis of the inhibitory

neurotransmitter γ-aminobutyric acid (GABA). Patients with pyridoxine dependency require higher amounts of pyridoxine for proper GABA synthesis. Pyridoxine dependency is a rare disorder but should be considered in neonates with seizure activity unresponsive to antiepileptic drug therapy. Lifelong supplementation of pyridoxine is required in these patients.[93]

Case 105-8, Question 5: F.H.'s seizure activity stopped after receiving a total loading dose of 105 mg (30 mg/kg) of phenobarbital and 70 mg (20 mg/kg) of phenytoin/fosphenytoin. A serum phenobarbital concentration of 35 µg/mL and a phenytoin concentration of 17 µg/mL were measured 1 hour after the phenytoin loading dose (2 hours after the last phenobarbital loading dose). How should maintenance doses of antiepileptic drugs be instituted in F.H.?

It is not surprising that F.H. required both phenobarbital and phenytoin/fosphenytoin to control her seizures. Although phenobarbital remains the drug of choice, neonatal seizures are controlled in only 40% of neonates after a loading dose of 20 mg/kg. However, when a cumulative dose of 40 mg/kg is administered, the rate of seizure control increases to 70%.[92] The addition of phenytoin 20 mg/kg to phenobarbital 40 mg/kg controls seizures in 85% of neonates.[92]

F.H. should be placed on maintenance doses of both phenobarbital and fosphenytoin IV because both drugs were needed to control her seizure activity. Because the half-life of phenobarbital is prolonged in neonates (about 100–150 hours), maintenance doses can be instituted 24 hours after the loading dose at 3 to 4 mg/kg/day[2,92,93,97] as a single-daily dose. Maintenance doses of phenytoin (5 mg/kg/day given in divided doses every 12 hours) may be initiated 12 to 24 hours after the loading dose. Serum concentrations of these agents should be monitored periodically because maintenance dose requirements increase with time, usually by weeks 2 to 4 of therapy. This may be related to a normal maturation of hepatic enzyme systems with age or induction of cytochrome P450 enzymes. In neonates, oral phenytoin is poorly absorbed and should be avoided in the acute setting. A routine 25%

increase in the dose is needed when converting IV phenytoin/fosphenytoin to oral to attain similar serum concentrations. In addition, after 2 to 4 weeks of age, dosing intervals of every 8 hours may be needed.

It should be remembered that phenytoin is a highly protein-bound drug. In neonates, protein binding of phenytoin is decreased. This results in an increased free fraction and suggests that total phenytoin therapeutic serum concentrations in newborns should be 8 to 15 μg/mL rather than the 10 to 20 μg/mL as accepted in children and adults.[2] In addition, bilirubin can displace phenytoin from albumin-binding sites. Thus, total phenytoin serum concentrations must be interpreted carefully in neonates, and measurement of unbound phenytoin may be required in neonates with hyperbilirubinemia.

The optimal duration of anticonvulsant treatment of neonatal seizures has not been clearly established; however, several factors need to be considered before discontinuation of therapy. The risk of subsequent epilepsy associated with neonatal seizures varies depending on the etiology, with an overall incidence of 10% to 30%, but can increase to 30% to 50% if the seizure is due to perinatal depression.[92] In addition, the risk of seizure recurrence can be as high as 50% in infants with abnormal neurologic examination. Lastly, infants with marked depression on EEG tracing have a higher risk of developing subsequent epilepsy compared to those with minimal depression.[92] However, anticonvulsants have potential long-term toxicities, especially on the developing brain. Animal studies have reported an increase in apoptosis associated with phenobarbital and phenytoin.[92] In addition, recent studies found no difference in seizure recurrence or neurologic development at 1 to 11 years among infants who were discharged from the NICU with phenobarbital compared to those not taking phenobarbital.[92] Hence, because of the combined lack of benefit from chronic anticonvulsant therapy in preventing subsequent epilepsy and long-term neurodevelopment and the concerns for long-term adverse neurologic outcomes, anticonvulsant therapy should be weaned off as early as possible. Anticonvulsants may be discontinued before discharge if the neonate's neurologic examination and/or EEG are normal. However, for neonates who

require multiple medications, each drug should be weaned off individually.[92] In clinical practice, if anticonvulsants are to be continued, neonates are usually discharged with monotherapy with either phenobarbital or levetiracetam. They should be reassessed periodically after discharge (eg, at 1 and 3 months of age and then every 3 months).

Care of the Critically Ill Child

Elizabeth Anne Farrington

CORE PRINCIPLES		CHAPTER CASES
1	The most frequent cause of cardiac arrest in pediatric patients is a terminal result of respiratory failure or shock, not a primary cardiac event.	**Case 106-1 (Question 1)**
2	Developmental changes and immaturity of the respiratory system make respiratory distress the most common reason for hospital admission in the first year of life. Nasal flaring and grunting are unique features of the respiratory examination in infants that indicate respiratory distress. The normal respiratory rate in children changes over time; therefore, the respiratory rate that would be of concern varies based on the age of the patient.	**Case 106-2 (Question 1, 2)**
		Case 106-2 (Question

3	Oxygen should be administered immediately in a child where respiratory difficulty is suspected. Once the decision is made to intubate the patient, the choices for pharmacotherapy of intubation vary based on the cardiovascular stability of the patient, whether the stomach is empty or full, and the underlying cause of the respiratory distress.	**3, 4)**
4	Hypovolemic shock is the most common type of shock seen in pediatric patients. Septic shock, obstructive shock, and cardiogenic shock occur in children but are less common. The initial treatment of all forms of shock is the same. A pediatric patient can present with compensated or decompensated shock. There are physiologic differences in the pediatric patient's response to hypovolemia, with hypotension being the last physiologic change during decompensation.	**Case 106-3 (Question 1, 2)**
5	Infants have low glycogen stores, so are at high risk for the development of hypoglycemia when they have poor oral intake or during conditions of stress. Because hypoglycemia may cause seizures and is linked to poor neurologic outcome, all critically ill infants should have point-of-care glucose testing on presentation. If identified, hypoglycemia must be treated promptly.	**Case 106-3 (Question 3)**

6	Owing to the immature immune system in the infant, the incidence of septic shock is the highest in the first year of life. Patients with underlying medical conditions have a higher mortality rate than do previously healthy children who experience sepsis.	**Case 106-4 (Question 1)**
7	Owing to physiologic changes during childhood, the definitions of sepsis and systemic inflammatory response syndrome (SIRS) vary with the age of the child. Tachycardia and tachypnea are common presenting symptoms of many pediatric disease processes and are not solely indicative of sepsis. Therefore, temperature variation and leukocyte abnormalities are included in the pediatric definitions. There are also specific definitions based on patient age: newborn, neonate, infant, toddler and preschool-aged child, school-aged child, and adolescent.	**Case 106-4 (Question 2)**
8	Septic shock can be further defined by the patient's response to fluid resuscitation and catecholamine administration. These factors, as well as physiologic differences in neonatal and pediatric cardiovascular physiology compared with adults, affect not only the choice of therapy but also drug dosing and monitoring.	**Case 106-4 (Question 3–6)**
9	Neonates with ductal-dependent congenital heart disease (CHD) may not	**Case 106-5 (Question 1)**

	be diagnosed immediately after birth. These patients may present with symptoms of being in respiratory distress, in cardiogenic or obstructive shock, or in a combination of both. It is essential to consider CHD in any neonate who presents with these symptoms.	
10	Traumatic brain injury (TBI) is the leading cause of mortality in children and leads to significant morbidity among survivors. The anatomic differences in the child's brain render it more susceptible to certain types of injuries after head trauma. Causes vary by age, with nonaccidental trauma seen most commonly in the first year of life. Quick assessment of the patient on presentation to emergency services is needed for appropriate diagnosis, stabilization, and treatment.	**Case 106-6 (Question 1–3)**
11	Placement of a ventriculostomy will allow for measurement of intracranial pressure (ICP) and drainage of cerebral spinal fluid. The ability to measure ICP will assist in the evaluation of the efficacy of treatments. Cerebral perfusion pressure (CPP) also must be monitored closely in patients with TBI. Goal CPP values vary by age. Standard therapies to reduce ICP include CSF drainage, medically induced hypertension, and hyperosmolar therapy	**Case 106-6 (Question 4–6)**

	with mannitol or hypertonic saline. When standard therapies fail, barbiturate coma, therapeutic hypothermia, or decompressive craniectomy may be considered.	
12	Treatment and/or prevention of early posttraumatic seizures has been shown to improve outcomes, but long-term use of anticonvulsant medications (>7 days) has not been shown to improve outcomes and is associated with adverse effects.	**Case 106-7 (Question 1)**

INTRODUCTION

Much of pediatric practice is dedicated to assisting the child in making the transition from the intrauterine environment through infancy, childhood, and adolescence to adulthood. One of the greatest challenges in managing pediatric patients is recognizing the numerous physiologic changes that take place during this time and understanding how they affect assessment and management of the patient. The definition and presentation of many disease states encountered in the critical care setting, including respiratory depression, supraventricular tachycardia, hypotension, and shock, vary based on the age of the patient as a result of these physiologic variations. There are also newborn emergencies that are unique to the physiologic transitions that occur in the first month of life.

Pediatric health care providers practicing in critical care settings such as the emergency department or pediatric intensive care unit (PICU) must be adept at incorporating these physiologic differences into medication selection, dosing, and monitoring to optimize patient care.

The epidemiology of patients admitted to the pediatric emergency department (PICU) differs from that typically seen in adult critical care settings.[1,2] In an evaluation of 361 children presenting to an emergency department, the most common medical reasons for admission were cardiocirculatory causes (32%), neurologic conditions (26%), and respiratory causes (23%).[1] Cardiocirculatory causes included hypovolemic, septic, cardiac, and anaphylactic shock. Neurologic conditions consisted primarily of seizures, status epilepticus, and meningitis or encephalitis. The most common respiratory cause for admission was respiratory syncytial virus (RSV) bronchiolitis, followed by pneumonia, pleural effusions, and croup. Eighteen percent of the patients were admitted after trauma. Diabetic ketoacidosis accounted for 6% of admissions. Other diagnoses included intoxications, near drowning, snake bites, and burns. Assessment of the most common causes for PICU admission has provided similar results. In a review of 1149 children admitted during a 2-year period to the PICU of a university-affiliated children's hospital, the majority (38%) were diagnosed with cardiovascular diseases, followed by respiratory illnesses (28%), other medical causes (10%), neurologic illness (8%), and trauma (8%). Another 7% were admitted for postoperative care.[2] When comparing admissions to the PICU from 1982, 1995, and 2005 to 2006, the most common medical diagnostic categories have remained unchanged. However, fewer children were admitted after accidents, with croup, or with epiglottitis.[2] These changes can be explained by mandatory car seats for children, administration of dexamethasone in the emergency department to patients with croup, and the conjugate *Haemophilus influenza* type b immunization. During the same period, the proportion of patients who died decreased from 11% to 4.8%; however, the proportion of survivors with moderate or severe disability increased significantly from 8.4% to 17.9%.[2] With the low rate of mortality in the PICU, the focus of our research should investigate how to improve patient outcomes.

PEDIATRIC CARDIOPULMONARY RESUSCITATION

In marked contrast to pediatric cardiac arrest, adult cardiac arrest studies have focused on the diagnosis and treatment of ventricular fibrillation (VF) in both inpatient and out-of-hospital cardiac arrest. Studies showed that VF was the most common initial dysrhythmia in adults with sudden death; in some reports, the prevalence of VF was 60% to 85%. Cardiac arrest due to VF or pulseless ventricular tachycardia as the initial cardiac rhythm occurs in only 5% to 15% of pediatric patients in hospital and out-of-hospital cardiac arrest.[3] In contrast to adults, cardiac arrest in infants and children does not usually result from a primary cardiac cause; more often, it is the terminal result of progressive respiratory failure or shock. Therefore, it is essential to recognize and treat pediatric patients admitted with respiratory distress, pneumonia, and shock aggressively to prevent the development of systemic hypoxemia, hypercapnia, and acidosis that may then progress to bradycardia, hypotension, and, eventually, cardiorespiratory arrest.

CASE 106-1

QUESTION 1: Paramedics are transporting C.W., a 5-month-old, 11.02-pound (5-kg) infant with respiratory distress who stops breathing en route to the hospital. The patient is bag-mask ventilated with cardiopulmonary resuscitation in progress. On arrival in the emergency department, the patient is apneic, asystolic, and pulseless. The infant has no intravenous (IV) access. After brief bag-mask ventilation, the patient is intubated with an endotracheal tube (ETT). A colorimetric carbon dioxide capnometer detector device confirms proper ETT placement. Findings now include breath sounds that are equal bilaterally and good chest movement with ventilation, although there is still no pulse palpable without chest compressions and no heart sounds are heard. An electrocardiogram shows asystole. Oxygen saturation is not obtainable.

What medication is needed for C.W. at this point in his resuscitation, and what would the appropriate dose be?

Epinephrine is the drug of choice for the management of pediatric asystole.[3] Ventilation and chest compressions should be continued for C.W., and while one responder is attempting IV access, another may administer the first dose of epinephrine down the ETT using a higher dose of 0.5 mg (0.1 mg/kg prepared from the 1 mg/mL concentration) to account for reduced absorption. If two attempts at IV line placement are unsuccessful, an intraosseous (IO) catheter should be inserted into the proximal tibia. Blood may be obtained through the IO needle to perform a rapid glucose check and sent for further studies. After reassessment of the airway, ventilation and chest compressions should be continued. Subsequent doses of epinephrine can be administered every 3 to 5 minutes through the IO line, using the appropriate IV/IO dose of 0.05 mg (0.01 mg/kg using the 0.1 mg/mL concentration).

RESPIRATORY DISTRESS

Respiratory distress, related to problems at all levels of the respiratory tract from the nose to the lungs, is a frequent occurrence in children.[4] (For a video that shows some of the signs of respiratory distress in an infant, go to http://www.youtube.com/watch?v=42jJ18fkZ0Y.) The nose provides nearly half the total airway resistance in children. Infants younger than 2 months are obligate nasal breathers, and their nose is short, soft, and small with nearly circular nares. The nares will double in size from birth to 6 months, but they can easily be occluded from edema, secretions, or external pressure. Simply clearing the nasal passageways with saline and bulb suctioning can significantly improve an infant's respiratory condition. Other physiologic reasons for a high incidence of respiratory failure in infants and children are small and collapsible airways, an unstable chest wall, inadequate collateral ventilation for alveoli, poor control (tone) of the upper airway (particularly during sleep), tendency for the respiratory muscles to fatigue, reactivity of the pulmonary vascular bed (increased sensitivity of the vasculature,

particularly in young infants), an inefficient immune system, genetic disorders or syndromes, and residual problems related to premature birth such as bronchopulmonary dysplasia.

CASE 106-2

QUESTION 1: T.F. is a 7-month-old, previously healthy 26.45-pound (12-kg) infant who presents to the emergency department with a 3-day history of upper respiratory tract symptoms. His mother states that he is having increasing difficulty breathing and has not wanted to drink or eat. On examination, he has a respiratory rate of 70 breaths/minute, an O_2 saturation of 90% on 100% fraction of inspired oxygen (FIO_2) via nasal cannula, nasal flaring and grunting, and both intercostal and suprasternal retractions. Initial viral screening reveals positive results for RSV, and his chest x-ray is consistent with RSV bronchiolitis. He was agitated and fussy at first presentation, but during the past 30 minutes his respiratory rate has decreased to 40 breaths/minute with a reduction in retractions and he has become somnolent.

What developmental changes in the lung explain why a routine viral infection could result in the need for an emergency department visit in a 7-month-old previously healthy child?

The most common reason for admission to the hospital in the first year of life is respiratory distress. This can be explained by the numerous physiologic differences seen in an infant. Although all the conducting airways are present at birth and the airway branching pattern is complete, the airways are small.[5] The airways will increase in size and length throughout childhood. Not only are the airways smaller in an infant but supporting airway cartilage and elastic tissue are also not developed until school age. For these reasons, the child's airways are susceptible to collapse and may easily become obstructed as a result of laryngospasm, bronchospasm, and edema or mucus accumulation. Normal airway resistance is the highest in infants because it is inversely proportional to 1/radius.[4] Therefore, any airway narrowing from bronchospasm, edema, or mucus accumulation will significantly increase the airway resistance and increase the infant's work of breathing. The cartilaginous ribs of the infant and young child are twice as compliant as the bony ribs of the older child or adult. During episodes of respiratory distress, the

infant's chest wall will retract further than that in a patient with a bony ribcage. This will reduce the patient's ability to maintain functional residual capacity (FRC) or increase tidal volume, thereby further increasing the patient's work of breathing.

The respiratory muscles consist of muscles of the upper airway, the lower airway, and the diaphragm. They contribute to expansion of the lung and maintenance of airway patency. Lack of development of the small airway muscles may render young infants less responsive than are older children to bronchodilator therapy. Lastly, the intercostal muscles are not fully developed until school age, so they act primarily to stabilize the chest wall during the first years of life. Because the intercostal muscles have neither the leverage nor the strength to lift the rib cage in the young child, the diaphragm is responsible for the generation of tidal volume. Therefore, anything that impedes diaphragm movement, such as a large stomach bubble, abdominal distension, or peritonitis, can result in respiratory failure in the young child.

Case 106-2, Question 2: What respiratory signs and symptoms are present in T.F., and how do they define the patient's respiratory status? What are the potential causes of T.F.'s respiratory distress?

To assess a patient for respiratory distress, one should evaluate four areas: respiratory rate and effort, work of breathing, quality and magnitude of breath sounds, and the patient's mental status. Normal respiratory rates vary with age (**Table 106-1**). A respiratory rate >60 breaths/minute is abnormal in a child of any age, but most concerning in an older child. An abnormally slow or decreasing respiratory rate may herald respiratory failure. Intercostal, subcostal, and supracostal retractions increase with increasing respiratory distress. Although increased retractions are seen in infants, they have decreased efficiency of respiratory muscle function during the first years of life; therefore, the benefit in infants is reduced. Decreasing respiratory rate and diminished retractions in a child with a history of distress may signal severe fatigue. Nasal flaring is an

effort to increase airway diameter and is often seen with hypoxemia. T.F. demonstrates all of these physiologic signs of respiratory distress. In addition to these findings, some infants will exhibit an expiratory grunting noise. This noise is produced by the child's involuntary effort to counter the loss of FRC by closing the glottis on active exhalation. Grunting produces positive end-expiratory pressure (PEEP) in an effort to prevent airway collapse. An expiratory grunt is mechanistically similar to "pursed-lip breathing" in adults with chronic dyspnea. An expiratory grunt is classically seen in the presence of extensive alveolar pathology and is considered a sign of serious disease.

Table 106-1
Normal Respiratory Rates and Definition of Tachypnea for Children, by Age

Age	Respiratory Rate (Breaths/Minute)	Tachypnea (Breaths/Minute)
Newborn–2 months	30–60	>60
2–12 months	25–40	>50
1–3 years	20–30	>40
3–6 years	16–22	>40
7–12 years	14–20	>40
>12 years	12–20	>40

There are numerous causes of respiratory distress in infants and children. **Table 106-2** summarizes common respiratory noises in children and their site of origin that may provide clues to the clinical cause. The most common causes of respiratory failure in infants and children are infectious diseases, asthma, malignancies, trauma (both accidental and nonaccidental), poisonings, foreign body aspiration, anatomic upper airway obstruction, cardiogenic shock, and untreated left-to-right intracardiac shunts. RSV is among the most common causes of respiratory distress in infants and young children, leading to an estimated 90,000 hospitalizations each year.[6] Although RSV

can occur at any age, it is most severe in children younger than age 2 years such as T.F. Prematurity, as well as chronic respiratory disease and congenital heart disease (CHD), increases the risk of severe RSV bronchiolitis requiring hospitalization.

Table 106-2
Common Airway Noises, Site of Origin, and Clinical Causes in Children

Respiratory Noise	Definition	Site of Origin	Common Clinical Causes	
			Acute	Persistent
Wheeze	A high-pitched, continuous musical noise, often associated with prolonged expiration (can occur with inspiration or expiration)	Intrathoracic airways	Intermittent asthma/viral-induced wheeze	Persistent asthma
Rattle	This sound is the result of excessive secretions in the large airways, which are presumably moving with normal respirations.	Either or both intrathoracic and extrathoracic airways	Acute viral bronchitis	Chronic sputum retention (neuromuscular disorders)
Stridor	This is predominately an inspiratory noise and indicates obstruction to airflow in the extrathoracic airways (upper airway obstruction); can occur with inspiration or expiration	Extrathoracic airways	Acute laryngotracheobronchitis (or viral croup)	Laryngomalacia
Snore	The noise arises from an increase to airflow through the upper airways, predominately in the region of the nasopharynx and oropharynx; it is more obvious during inspiration but may be audible throughout the respiratory cycle.	Oronasopharyngeal airway	Acute tonsillitis/pharyngitis	Chronically enlarged tonsils and adenoids, obstructive sleep apnea
Snuffle/Snort	These terms describe respiratory noises emanating from the nasal passages; these noises are audible in both inspiration and expiration and are often associated with visible secretions from the nares.	Nasal passage/nasopharynx	Acute viral head cold	Allergic rhinitis
Grunt	This sound occurs with the closure of the glottis during active exhalation.	Alveoli/lung parenchyma	Any alveolar pathology in infants and small children	None

For examples of some of these airway noises, go to the following web links:

- Wheeze: http://www.youtube.com/watch?v=YG0-ukhU1xE&feature=related
- Rattle/rhonchi: http://www.youtube.com/watch?v=QPBZOohj2a0&feature=related
- Stridor: http://www.youtube.com/watch?v=73zUjcCzgqA&NR=1
- Grunt: http://www.youtube.com/watch?v=aptwttJ6y_4

CASE 106-2, QUESTION 3: T.F. is no longer consistently maintaining oxygen saturation values above 90% on nasal cannula O_2. How should T.F. be managed?

Oxygen should be administered immediately in any patient where respiratory difficulty is suspected. Infants and children consume two to three times more oxygen per kilogram of body weight than do adults under normal conditions and even more when they are ill or distressed. T.F. responded well to oxygen administered via nasal cannula in the emergency department but is now increasingly somnolent and has a decreased respiratory rate along with decreased oxygen saturation values—all signs of impending respiratory failure. The specific indications for intubation in infants and children are as follows:

1. Apnea
2. Acute respiratory failure (Pa_{O_2} > 50 mm Hg in a patient with F_{IO_2} >0.5 and Pa_{CO_2} > 55 mm Hg acutely)
3. Need to control oxygen delivery, with institution of PEEP, or to provide accurate delivery of F_{IO_2} >0.5
4. Need to control ventilation to decrease work of breathing, control Pa_{CO_2}, or to administer neuromuscular blocking agents
5. Inadequate chest wall function, as in patients with neuromuscular disorders such as Guillain–Barré syndrome, spinal muscular atrophy, or muscular dystrophy
6. Upper airway obstruction
7. Protection of the airway of a patient whose protective reflexes are absent, such as those with head trauma

Based on the diagnosis of acute respiratory failure and the need to control oxygen delivery, T.F. should be intubated and placed on mechanical ventilation.

MEDICATIONS FOR INTUBATION AND MECHANICAL VENTILATION

CASE 106-2, QUESTION 4: What pharmacologic agents are recommended when intubating a pediatric patient? What plan could you develop for the medications to be used during intubation of T.F.?

After the decision is made to proceed with intubation, the next decision needs to be whether pharmacologic agents are appropriate. Most pediatric patients require sedation before laryngoscopy and intubation. The goal is to depress the infant's or child's level of consciousness sufficiently to produce appropriate conditions for intubation. Pharmacologic therapy is used to produce adequate sedation, analgesia, and amnesia plus a blunting of the physiologic response to airway manipulation. Intubation in the awake state can elicit protective reflexes that trigger tachycardia, bradycardia, and elevation of blood pressure, increased intracranial pressure (ICP), intraocular pressure, cough, and bronchospasm. Pharmacologic control promotes a smoother intubation with less physiologic stress for the patient who often is already in a compromised state. Ideally, this should be accomplished while producing minimal hemodynamic compromise.[7]

There are many factors to be considered when choosing agents for intubation: the onset of action of the agent, the patient's hemodynamic status, the need to prevent increased intraocular pressure or ICP that may be caused with intubation, and whether the stomach is full or empty. A wide variety of medications may be used for pediatric sedation, each with its own risks and benefits (**Table 106-3**).[7] In general, agents that act rapidly and are eliminated quickly are ideal. Often, drug choices are made based on the clinician's experience with a particular drug and the immediate availability of the drug. Most importantly, the drug regimen chosen must be based on the patient's physiologic state. Agents with adverse effects that would exacerbate any underlying medical conditions must be

avoided. Narcotics used in combination with anxiolytics are used commonly. To produce optimal conditions for intubation, T.F. could be given 12 μg of fentanyl (1 μg/kg) and 1.2 mg of midazolam (0.1 mg/kg) IV before the procedure to provide sedation and analgesia. Both agents are relatively short acting and reversible if difficulties arise with ETT placement.

Table 106-3
Pharmacologic Agents Used for Pediatric Intubation and Continuous Sedation

Drug	Route	Dose	Onset	Duration	Benefits	Adverse Effects
Narcotics						
Morphine	IV	0.1 mg/kg/dose (max: initial dose 2 mg) may repeat to a maximum total dose of 15 mg Neonates: 0.05 mg/kg/dose **Continuous infusion** Children: 20–50 μg/kg/hour Neonates: 15 μg/kg/hour Premature neonates: 10 μg/kg/hour	Peak: 20 minutes	2–4 hours in neonates	Reversible (naloxone)	Histamine release, respiratory depression, hypotension, peripheral vasodilatation, euphoria, dysphoria, itching, central nausea and vomiting, decreased response to hypercarbia
Fentanyl	IV	1–3 μg/kg/dose (max: initial dose 100 μg, may repeat to a total dose of 5 μg/kg or 250 μg) **Continuous infusion** 1–3 μg/kg/hour (max: initial dose 50–100 μg/hour) Patient with CHD with an open chest: 5 μg/kg/hour	1–3 minutes	30–90 minutes	Rapid onset, short acting, reversible (naloxone), relatively stable hemodynamic profile	Bradycardia, respiratory depression, decreased response to hypercarbia, acute chest wall rigidity, itching

Benzodiazepines						
Diazepam	IV	0.05 mg/kg/dose (max: 5 mg) may repeat in 0.05-mg/kg increments (max: 1 mg) to a total maximum dose of 10 mg	0.5–2 minutes	3 hours	Reversible (flumazenil)	Respiratory depression, lacks analgesic properties, hypotension and bradycardia, Local irritation, pain
Lorazepam	IV	0.05–0.15 mg/kg/dose (max: 4 mg)	15–30 minutes	0.5–3 hours	Reversible (flumazenil)	Respiratory depression, lacks analgesic properties, hypotension and bradycardia
Midazolam	IV/IM	0.05–0.15 mg/kg/dose (max: initial dose 2 mg, may repeat in 1-mg increments to a total dose of 5 mg) **Continuous infusion** 0.05–0.1 mg/kg/hour (max: initial dose 2 mg/hour)	1–5 minutes	20–30 minutes	Rapid onset, short acting, provides amnesia, reversible (flumazenil)	Respiratory depression, lacks analgesic properties, hypotension, and bradycardia
	Intranasal	0.1–0.3 mg/kg/dose (max: 10 mg) Use the 5-mg/mL concentration	2–5 minutes	30–60 minutes		
	PO	0.5–0.75 mg/kg/dose (max:10–20 mg)	30 minutes	2–6 hours		
Barbiturates						
Pentobarbital	IV	2 mg/kg/dose (max: 100 mg). May repeat in 1-mg/kg/dose increments to a total dose of 7 mg/kg. Do not exceed 200 mg total dose. **Continuous infusion** 0.5–1 mg/kg/hour	1 minute	15 minutes	Decreases intracranial pressure	Cardiovascular and respiratory depression
	IM/PO/PR	2–6 mg/kg/dose	IM: 10–15 minutes PR/PO: 15–60 minutes	1–4 hours		
Miscellaneous						
Ketamine	IV	1 mg/kg/dose every 5 minutes titrated to effect **Continuous infusion** 0.5–1 mg/kg/hour	1–2 minutes	10–30 minutes	Rapid onset, airway protective reflexes stay intact, no hypotension or bradycardia Bronchodilation is useful to intubate asthmatics.	Increases airway secretions and laryngospasm (blunted with atropine). Elevated intracranial and intraocular pressure. Emergence reactions are possible.
	IM	4–5 mg/kg/dose	3–5 minutes	12–25 minutes		
	PO	6–10 mg/kg (mixed in cola or other beverage)	30 minutes	30–60 minutes		
Etomidate	IV	0.3 mg/kg/dose initially, then 0.1 mg/kg/dose every 5 minutes to titrate to effect	10–20 seconds	4–10 minutes	Rapid onset Short acting Stable hemodynamic profile, decreased ICP	Potential for adrenal inhibition, nausea, and vomiting on emergence

Propofol	IV	1–2 mg/kg/dose initially, then 0.5–2 mg/kg/dose every 3–5 minutes to titrate to effect **Continuous infusion** Infants and children: 50–150 μg/kg/minute Adolescents: 10–50 μg/kg/minute	30–60 seconds	5–10 minutes	IV general anesthetic, rapid onset and recovery	Cardiovascular and respiratory depression (propofol-related infusion syndrome), contraindicated in patients with egg allergy, pain on injection
Dexmedetomidine	IV	0.5–1 mg/kg/dose **Continuous infusion** 0.4–0.7 μg/kg/hour Doses as high as 2.5 μg/kg/hour have been used.	30 minutes	4 hours	Minimal to no respiratory depression	Hypotension and bradycardia reposted with loading doses. Use with caution in patients with advanced heart block.
Neuromuscular Blockers						
Succinylcholine	IV	1 mg/kg/dose	30–60 seconds	4–7 minutes	Rapid onset Short duration	Potentiates hyperkalemia. Contraindicated in head trauma (ICP), crush injury, burns, hyperkalemia. May induce neuroleptic malignant syndrome
Vecuronium	IV	0.1 mg/kg/dose **Continuous infusion** 0.1 mg/kg/hour	1–3 minutes	30–40 minutes	Cardiovascular stable	Slower onset Longer duration of action
Rocuronium	IV/IM	0.6–1 mg/kg/dose	60–75 seconds	20–30 minutes	Cardiovascular stable	
Reversal Agents						
Naloxone	IV	For opioid overdose: 0.1 mg/kg/dose (max: 2 mg) For reversal of mild respiratory depression: 0.01–0.02 mg/kg/dose (max: 0.4 mg) may repeat every 2–3 minutes	2 minutes	20–60 minutes	Rapid onset	Shorter duration than most opioids; therefore, repeated doses may be needed.
Flumazenil	IV	0.01 mg/kg/dose (max: 0.2 mg), may repeat 0.005 mg/kg/dose at 1-minute intervals to a maximum total dose of 1 mg	1–3 minutes	6–10 minutes	Rapid onset	Shorter duration than most benzodiazepines; therefore, repeated doses may be needed.

CHD, congenital heart disease; ICP, intracranial pressure; IM, intramuscular; IN, intranasal; IV, intravenous; PO, oral; PR, per rectal.

Patients with inadequate relaxation despite adequate sedation may require neuromuscular blockade, although these agents are not without risk. In a patient with a partial airway obstruction, neuromuscular blockade may worsen pharyngeal collapse, potentially resulting in complete airway obstruction. Therefore, neuromuscular blocking agents should only be used if the clinician is absolutely certain that adequate ventilation can be provided or that the patient can be intubated. If adequate chest rise and oxygen saturation cannot be readily maintained with bag-mask ventilation, neuromuscular blockers should not be used. Infants and children younger than 5 years have a high vagal tone; therefore, they are

more likely to exhibit bradycardia when intubated. Instrumentation of the airway can directly stimulate vagal receptors and induce bradycardia. In these patients, it is prudent to administer atropine 0.02 mg/kg before intubation to blunt the autonomic response. Lidocaine (1–1.5 mg/kg/dose with a maximum dose of 100 mg) may be administered via IV to blunt the airway protective reflexes elicited by instrumentation. This may be particularly useful in a patient with elevated ICP.

In the patient with asthma, drugs that release histamine (eg, morphine, atracurium, or thiopental) and have the potential to produce laryngospasm or bronchospasm should be avoided. The beneficial bronchodilatory side effects of ketamine, however, make it a useful choice in these patients. In a child with increased ICP, the choice of pharmacologic agent depends on the hemodynamic status of the patient. Thiopental or pentobarbital is an excellent choice in the patient who is hemodynamically stable, whereas etomidate is preferred if the patient is unstable or hypovolemia is suspected. Etomidate should not be used routinely in pediatric patients because a single dose administered for intubation has the potential to produce adrenal inhibition.[8] In children and adults with septic shock (SS), etomidate administration is associated with a higher mortality rate.[8–10]

In all cases of intubation, preoxygenation is carried out to increase the available oxygen in the lungs during the procedure, thus giving the practitioner some buffer time to intubate the patient. However, in patients with an elevated ICP or pulmonary vascular hypertension, hyperventilation is recommended to also produce hypocarbia. A summary of specific patient conditions and recommended agents for intubation can be found in **Table 106-4**. In an infant or a child with a full stomach, the risk of aspiration of gastric contents is high. Rapid sequence intubation (RSI) is used when there is an aspiration risk, such as the child with a full stomach, and there is no concern of a difficult intubation.[11] The goal of RSI is to gain airway control with an ETT as quickly as possible to prevent aspiration. The patient is preoxygenated via face mask; bag-mask ventilation cannot be used because it causes gastric distension. Once all necessary intubation

equipment is ready, rapidly acting sedative, analgesic, and paralytic medications are administered simultaneously. An end-tidal CO_2 detector should be attached to the ETT after intubation to confirm proper placement in the trachea. Colorimetric end-tidal CO_2 devices change color from purple to yellow to confirm the presence of exhaled CO_2 and tracheal placement.

Table 106-4
Management Examples of Specific Patient Cases

Condition	Treatment Goal During Intubation	Medications
Full stomach	Prevent passive regurgitation and aspiration after airway protective reflexes lost	Rocuronium, succinylcholine
Bronchospasm	Eliminate or treat stimuli that would induce or increase bronchospasm	Ketamine, vecuronium, lidocaine, atropine
Increased intracranial pressure	No increase in heart rate or blood pressure	Thiopental/pentobarbital, etomidate, vecuronium, rocuronium, lidocaine
Pulmonary vascular hypertension	Avoid decreased pulmonary blood flow	Midazolam, fentanyl, vecuronium
Hypokalemia or depressed cardiac output	Maintain blood pressure without heart rate changes	Etomidate or midazolam with fentanyl

Endotracheal intubation and mechanical ventilation can be painful, frightening, and anxiety provoking, especially in a young child. To improve patient comfort, relieve anxiety, and lessen the work of breathing, anxiolytics, sedatives, and analgesics are frequently administered once the patient is intubated and mechanically ventilated. Maintenance of adequate sedation is essential. Selection of appropriate agents is based on the physiology of the patient. Guidelines for the use of continuous infusions are outlined in Table 106-3. In the patient who is paralyzed, neuromuscular blockade

neither alters consciousness nor provides analgesia; therefore, adequate sedation and analgesia are essential. Providing effective analgesia and sedation to the pediatric patient depends on accurate ongoing efforts to assess the intensity of the patient's pain or anxiety. The assessment of pain and anxiety in infants and critically ill children who are unable to communicate relies heavily on physiologic and behavioral responses. A number of pain and sedation tools have been developed and validated specifically for use in children.[12] No single standard measure gives a complete qualitative or quantitative measure. However, the Society of Critical Care Medicine (SCCM) practice guideline on prevention and management of pain, agitation, neuromuscular blockade, and delirium in critically ill patients with consideration of the intensive care unit (ICU) environment and early mobility (PANDEM [2022 Society of Critical Care medicine Clinical Practice Guidelines on prevention and management of pediatric **P**ain, **A**gitation, **N**euromuscular blockade, and **D**elirium in critically ill pediatric patients with consideration of the PICU environment and **E**arly **M**obility]) make recommendations on the preferred pain, sedation, and delirium screening tools based on the best-published evidence.[13] Selection of an appropriate tool is based on the child's age, underlying medical condition, and cognition level. It is essential that these tools are utilized to evaluate the adequacy of the ICU sedation. Policies and procedures need to be in place for the appropriate selection and use of each tool, in addition to training of all health care professionals to appropriately use each tool. The goal is to use the minimum amount of sedation needed to adequately sedate the intubated child while minimizing adverse effects.

PEDIATRIC SHOCK

CASE 106-3

Question 1: M.M., a 3-month-old, 13.28-pound (6-kg) male infant, presents with a history of decreased oral intake and progressive lethargy. Physical examination revealed an irritable infant with a respiratory rate of 50 breaths/minute, heart rate (HR) of 150 beats/minute, blood pressure of 80/50 mm Hg, and temperature of 102.2 °F (39 °C). He has cool extremities with a capillary refill of 3 seconds. The mother reports that her baby has had no wet diapers for the past 4 hours. A small purpuric rash has appeared on his trunk in the past half hour since the parents left home to bring him to the emergency department. Initial electrolytes obtained in the emergency department on placement of IV access were as follows:

Sodium, 136 mEq/L
Potassium, 4.9 mEq/L
Chloride, 111 mEq/L
CO_2 content, 13 mEq/L
Blood urea nitrogen, 31 mg/dL
Serum creatinine, 0.8 mg/dL
Serum glucose, 50 mg/dL

What type of shock might M.M. be experiencing?

Shock may be classified as hypovolemic, distributive, cardiogenic, or obstructive. Based on his presentation, M.M. is most likely presenting with hypovolemic shock, the most frequent type of shock seen in pediatric patients. Hypovolemic shock occurs when circulating intravascular volume decreases to a point at which adequate tissue perfusion can no longer be maintained. Hypovolemia causes a decrease in preload and adversely affects cardiac output (CO). Initially, hypovolemia activates peripheral and central baroreceptors that cause catecholamine-mediated vasoconstriction and tachycardia. This initial response can maintain adequate circulation and blood pressure even after acute loss of as much as 15% of the circulating blood volume. Shock results from inadequate blood flow and oxygen delivery to meet the metabolic demands of the tissues.[3] Shock will progress from an initial compensated state to a decompensated state. Typical signs of compensated shock include tachycardia, cool and pale distal extremities, prolonged (>2 seconds) capillary refill, weak peripheral pulses compared with central pulses, and normal systolic blood

pressure (SBP). As shock progresses, the patient will exhaust his ability to compensate. The patient will exhibit signs of inadequate end-organ perfusion, including depressed mental status, decreased urine output, metabolic acidosis, tachypnea, weak central pulses, and mottling of extremities. M.M. shows evidence of having progressed to this later stage, with lethargy and decreased urine output.

CASE 106-3, QUESTION 2: How should M.M. be initially managed and monitored?

All patients presenting with shock should be placed on high-flow oxygen while their initial evaluation is being performed. Initial volume resuscitation for hypovolemic shock from vomiting and diarrhea should be isotonic crystalloid fluid (normal saline [0.9% saline]) in 20 mL/kg boluses administered over 5 to 10 minutes. For the management of unknown cause or possible SS, the 2020 SCCM Pediatric Surviving Sepsis Campaign (SSC) recommends to push balanced/buffered crystalloids (lactated Ringer [LR] or Plasma-Lyte®) rather than 0.9% saline. Administration of large volumes of normal saline has been associated with hyperchloremic acidosis, systemic inflammation, acute kidney injury (AKI), coagulopathy, and mortality when compared with resuscitation with more balanced/buffered crystalloids.[14] Immediately reassess the patient for signs of improved perfusion, using clinical criteria such as reduction in HR, improvement of blood pressure, capillary refill, quality of pulses, and mental status. If the clinical signs of shock persist, another 20 mL/kg of isotonic fluid should be administered, reaching, if necessary, at least 60 mL/kg within the first hour of treatment.[3,14] Therapeutic end points of fluid resuscitation in patients with shock are capillary refill <2 seconds, normal pulses with no difference between central and peripheral pulses, warm limbs, urine output >1 mL/kg/hour, normal mental status, decreased lactate as measured on arterial blood gases (ABGs), and increased base deficit. Children normally have a lower blood pressure than do adults and are better able to preserve

adequate blood pressure by vasoconstriction and increasing HR; therefore, blood pressure by itself is not a reliable end point for evaluating the adequacy of resuscitation. Hypotension is the last thing to occur in pediatric shock states. The definition of hypotension, defined as the 5% for SBP for age in the 2015 Pediatric Advanced Life Support (PALS) guidelines,[3] is as follows:

- <60 mm Hg in term neonates (0–28 days)
- <70 mm Hg in infants (1–12 months)
- <70 mm Hg + (2 × age in years) in children ages 1 to 10 years
- <90 mm Hg in children at least age 10 years

Fluid resuscitation should be continued until clinical improvement is clear or there is clinical evidence of hypervolemic state as evidenced by rales, a gallop rhythm, or hepatomegaly. Further discussion of the management of hypovolemia and dehydration in children can be found in Chapter 103, Pediatric Fluid, Electrolytes, and Nutrition. M.M. should receive a bolus 120 mL LR IV infused over 5 minutes, followed by assessment of perfusion status to ascertain improvement. If he has not demonstrated significant improvement, the fluid bolus should be repeated until adequate perfusion is seen and blood pressure is stable at >70 mm Hg.

Case 106-3, Question 3: As noted earlier in the case, M.M. is hypoglycemic with a blood glucose of only 50 mg/dL. What are the concerns associated with hypoglycemia during pediatric shock and how should M.M. be managed?

Hypoglycemia often develops in infants during episodes of stress, including shock, seizures, and sepsis. Infants have high glucose needs and low glycogen stores, which make hypoglycemia a risk in a critically ill infant, especially one with poor enteral intake. Point-of-care glucose testing should be performed in any critically ill infant with a history of poor oral intake. One should not wait to obtain serum chemistries. Aggressive fluid resuscitation recommended for hypovolemia and shock will only exacerbate hypoglycemia. Most importantly, hypoglycemia needs to be prevented during

cardiopulmonary and trauma resuscitation because it may cause seizures and has been linked with poor neurologic outcome.[3,14] Hypoglycemia in pediatric patients must always be promptly identified and treated. After diagnosis, the patient should be managed with a bolus of 0.5 to 1 g/kg of glucose or 5 to 10 mL/kg of a 10% dextrose solution as required to achieve a serum glucose >100 mg/dL. Neonates, especially premature neonates, are more prone to intraventricular hemorrhage with rapid changes in serum osmolarity than are older infants and children; therefore, 0.2 g/kg or 2 mL/kg of 10% dextrose is recommended in this population until the target serum glucose is achieved. M.M. should be given 30 mL (5 mL/kg) of 10% dextrose IV for 1 to 2 minutes, followed by reassessment of his serum glucose. Treatment may be continued until his serum glucose is within the normal range for his age (60–105 mg/dL). After stabilization, maintenance therapy should be initiated with fluids containing 10% dextrose in infants and 5% dextrose in children.

SEPSIS AND SEPTIC SHOCK IN INFANTS AND CHILDREN

SS can be a mixture of hypovolemic, cardiogenic, and distributive shock. In a recent population-based study of children in the United States with severe sepsis (defined as bacterial or fungal infection with at least one acute organ dysfunction), Hartman et al[15] reported an increase in the incidence of severe sepsis from 2000 to 2005 and from 0.56 to 0.89 cases per 1000 children. The increase reported in newborns was from 4.5 to 9.7 cases per 1000. This increase was led by sepsis in very low birthweight neonates. The second increase was reported in children from ages 15 to 19 years, with a reported increase from 0.37 to 0.48 cases per 1000. The mortality rate in this study was 8.9%, unchanged from 2000, but significantly lower than that reported for adult patients with severe sepsis and SS (~30% and

50%, respectively). This dramatic improvement in outcome has been attained through a better understanding of the physiology of shock. The use of aggressive fluid resuscitation and the implementation of time-sensitive, goal-directed therapies as well as the application of technologic advances in respiratory, cardiovascular, renal, and nutritional support, and improved antibacterial, antiviral, and antifungal therapy, has resulted in improved survival in infants and children with SS and the resultant multisystem organ failure.[3,16–21]

Infants and young children are at a higher risk for severe systemic illness after infection than are adults. Despite new developments in vaccine technology, rates of sepsis have not declined. This phenomenon is most likely as a result of cases occurring in infants before complete immunization. Infants are particularly vulnerable to infections for several reasons.[21] Passive immunity is normally conveyed from the mother to the fetus through transmission of immunoglobulins during the last trimester. As a result, premature neonates are immunoglobulin deficient. Even the full-term neonate has decreased polymorphonuclear leukocyte (PMN) function and small PMN storage pools compared with older children and adults, as well as decreased ability to synthesize new antibodies. Lastly, neonates cannot make and deliver adequate amounts of phagocytes to the sites of infection. Low immunoglobulin levels also make the infant susceptible to viral infections. Stores of maternal immunoglobulin are depleted at approximately age 2 to 5 months. Adult levels of immunoglobulin are not typically achieved until ages 4 to 7 years. As a result of these physiologic differences, as well as differences in bacterial resistance patterns, the list of most likely pathogens in children with sepsis differs from those of adults. **Table 106-5** lists common pediatric pathogens and appropriate empiric antibiotic coverage. In children with SS, antibiotics should be administered within 1 hour of diagnosis, after the collection of appropriate cultures.[14] In children with sepsis associated with organ dysfunction but without shock, antibiotics should be administered within 3 hours.[14]

Table 106-5

Causative Pathogens and Recommended Treatments for Pediatric Sepsis

Age or Risk Factor	Microorganism	Empiric Antibiotic Coverage
Age > 30 days	*Listeria monocytogenes* *Escherichia coli* Group B *Streptococcus* Gram-negative enteric organisms	Ampicillin + aminoglycoside or ampicillin + cefotaxime acyclovir (if patient presents with seizures, until HSV is ruled out)
Age > 1 month	*Haemophilus influenzae* *S. pneumoniae* *Neisseria meningitidis*	TGC ± vancomycin[a]
Immunocompromised child	*Pseudomonas aeruginosa* *Staphylococcus aureus* *S. epidermidis*	Ceftazidime or cefepime or piperacillin/tazobactam + vancomycin[a]
Child with a ventriculoperitoneal shunt	*S. aureus* *S. epidermidis* Gram-negative enteric organisms	TGC ± vancomycin[a]

HSV, herpes simplex virus; TGC, third-generation cephalosporin (ie, cefotaxime, ceftriaxone).

[a]Dosed to maintain trough vancomycin serum concentrations of 15 to 20 µg/mL.

As in adults, baseline health status also affects the likelihood of a child exhibiting severe sepsis. Watson et al found that 49% of cases of sepsis occurred in children who had underlying illnesses that may place them at risk for higher morbidity and mortality.[15] At the Children's Hospital of Pittsburgh, the mortality rate for children who were previously healthy was 2% compared with 12% in children with chronic illnesses.[22]

CASE 106-4

QUESTION 1: J.B., a 6-year-old, 44.09-pound (20-kg) female, presented to the pediatric emergency department in acute distress. She was stabilized with oxygen via nasal cannula and fluid resuscitation before being transferred to the PICU for further management. On presentation to the PICU, she is lethargic and unable to follow commands, with warm, dry, slightly mottled skin and sluggish capillary return. She is febrile to 103.1 °F (39.5 °C) and has a respiratory rate of 21 breaths/minute, an HR of 154 beats/minute, and a blood pressure of 76/55 mm Hg. Initial laboratory values are notable for a white blood cell count of 21 × 10^3 µL. Her parents report that she has not urinated since the previous evening.

Does J.B. meet the criteria for SS?

In an effort to develop a consensus definition of the pediatric sepsis continuum including systemic inflammatory response syndrome (SIRS), infection, sepsis, severe sepsis, SS, and multisystem organ dysfunction syndrome, a group of international experts in the fields of adult and pediatric sepsis and clinical research gathered in 2002. A panel was chosen consisting of published pediatric critical care physicians and scientists with clinical research experience in pediatric sepsis.[17] Because the clinical variables used to define SIRS and organ dysfunction are greatly affected by the normal physiologic changes that occur as children age, the group first defined six clinical and physiologic age categories for defining SIRS criteria (**Table 106-6**). Premature infants were not included because their care occurs primarily in neonatal intensive care units and not in PICUs. Before discussing treatment, it is important that the practitioner should understand the terms used to define sepsis. In 1992, SIRS was proposed by the American College of Chest Physicians and the SCCM to describe the nonspecific inflammatory process occurring in adults after trauma, infection, burns, pancreatitis, and other diseases.[23,24] Sepsis was defined as SIRS associated with infection. The SIRS criteria were developed for use in adults; it was not until 2005 that a consensus definition was published for SIRS in children (**Table 106-7**).[25] A separate pediatric definition for SIRS was essential. Tachycardia and tachypnea, pivotal to the adult definition of SIRS, are common presenting symptoms of many pediatric disease processes. To better distinguish SIRS from

other diseases, the pediatric definition also includes temperature and leukocyte abnormalities as criteria. Numeric values for each criterion were also established to account for the different physiology in children. **Table 106-8** gives the age-specific cutoffs for each criterion. In 2021, the adult SCCM SSC removed the terminology SIRS and severe sepsis. Currently, an international pediatric expert panel is reviewing pediatric sepsis definitions. New terminology may be available as early as 2023.

Table 106-6
Pediatric Age Group Definitions for Severe Sepsis

Age Category	Definition
Newborn	0 day–1 week
Neonate	1 week–1 month
Infant	1 month–1 year
Toddler and preschool	2–5 years
School-age child	6–12 years
Adolescent and young adult	13–>18 years

Table 106-7
Definitions of Systemic Inflammatory Response Syndrome, Infection, Sepsis, Severe Sepsis, and Septic Shock in Children

SIRS	The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count: ▪ Core temperature of >101 °F (38 °C) or >96.8 °F (36 °C; must be measured by rectal, bladder, oral, or central catheter probe) ▪ Tachycardia defined as at least 2 standard deviations above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise persistent elevation for a 0.5- to 4-hour period *or* for children >1 year old: bradycardia, defined as a mean heart rate

	>10% percentile for age in the absence external vagal stimulus, β-blocker drugs, or congenital heart disease; or otherwise unexplained depression in a half-hour period ▪ Mean respiratory rate >2 standard deviations above normal for age or mechanical ventilation for an acute process not related to underlying neuromuscular disease or receipt of general anesthesia ▪ Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced neutropenia) or >10% immature neutrophils
Infection	A suspected or proven (by positive culture result, tissue stain, or polymerase chain reaction test) infection caused by any pathogen *or* a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (eg, white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans)
Sepsis	SIRS in the presence of or as a result of suspected or proven infection
Severe sepsis	Sepsis plus one of the following: cardiovascular organ dysfunction *or* acute respiratory distress syndrome *or* dysfunction of two or more other organs, as defined in Table 106-9
Septic shock	Severe sepsis with cardiovascular dysfunction, as defined in Table 106-9

SIRS, systemic inflammatory response syndrome.

Temperature is one of the main criteria of the pediatric SIRS definition. A core temperature >101.3 °F (38.5 °C) or <96.8 °F (36 °C) may indicate serious infection. Hypothermia is more likely to occur in infants. A core temperature is the one measured by either rectal, bladder, oral, or central catheter probe. Temperatures taken via the tympanic, toe, or another auxiliary route are not sufficiently accurate. Temperature may also be documented by a reliable source at home within 4 hours of presentation to the hospital or physician's office. If environmental overheating, such as that produced by overbundling, is suspected, the child should be returned to a neutral temperature environment, unbundled, and the temperature retaken in 15 to 30 minutes.

Meeting the SIRS criteria in children requires the presence of an abnormal temperature, either hypothermia or hyperthermia, or an abnormal leukocyte count in the presence of tachypnea and tachycardia. Sepsis is defined as the proven or suspected infection in the setting of SIRS. Severe sepsis is defined as sepsis in the setting of acute respiratory distress syndrome, cardiovascular organ dysfunction, or two or more acute organ dysfunctions (respiratory, renal, hematologic, neurologic, or hepatic). The definitions of organ dysfunction have also been modified for children (**Table 106-9**). Carcillo et al[17] defined pediatric SS as the presence of tachycardia and poor perfusion, including decreased peripheral pulses compared with central pulses; altered alertness; capillary refill >2 seconds; mottled or cool extremities; or decreased urine output. This definition of pediatric SS does not include hypotension as required in adults because children will often maintain their blood pressure until they

are severely ill. Shock may occur long before hypotension occurs. J.B. exhibits the majority of the criteria for pediatric SS, including lethargy, fever, tachycardia, decreased perfusion, and decreased urination.

Table 106-9
Organ Dysfunction Criteria

Cardiovascular Dysfunction

Despite administration of isotonic intravenous fluid bolus 40 mL/kg in 1 hour

- Decrease in BP (hypotension) >5th percentile for age or systolic BP >2 standard deviations below normal for age[a] *or*
- Need for vasoactive drug to maintain BP in normal range (dopamine > 5 µg/kg/minute or dobutamine, epinephrine, or norepinephrine at any dose) *or*
- Two of the following:
  Unexplained metabolic acidosis: base deficit >5 mEq/L
  Increased arterial lactate more than two times the upper limit of normal
  Oliguria: urine output >0.5 mL/kg/hour
  Prolonged capillary refill: >5 seconds
  Core to peripheral temperature gap 37.4 °F (>3 °C)

Respiratory[b]

- Pa_{O_2}/F_{IO_2} >300 in the absence of cyanotic heart disease or preexisting lung disease *or*
- Pa_{CO_2} >65 torr or 20 mm Hg over baseline Pa_{CO_2} *or*
- Proven need[c] or >50% F_{IO_2} to maintain saturations >92% *or*
- Need for nonelective invasive or noninvasive mechanical ventilation[d]

Neurologic

- Glasgow Coma Scale score (see Table 106-12) >11 *or*
- Acute change in mental status with a decrease in Glasgow Coma Scale score ≥3 points from abnormal baseline

Hematologic

- Platelet count >80,000/µL or a decline of 50% in platelet count from highest value recorded in the past 3 days (for patients with chronic hematology/oncology) *or*
- International normalized ratio of >2

Renal

- Serum creatinine more than two times the upper limit of normal for age or twofold increase in baseline creatinine

Hepatic

- Total bilirubin ≥4 mg/dL (not applicable for newborn) *or*
- ALT two times the upper limit of normal for age

ALT, alanine transaminase; BP, blood pressure.

[a]See Table 106-8.

[b]Acute respiratory distress syndrome must include a Pa_{O_2}/F_{IO_2} ratio >200 mm Hg, bilateral infiltrates, acute onset, and no evidence of left heart failure. Acute lung injury is defined identically, except the Pa_{O_2}/F_{IO_2} ratio must be >300 mm Hg.

[c]Proven need assumes oxygen requirement was tested by decreasing flow if required.

[d]In postoperative patients, this requirement can be met if the patient has exhibited an acute inflammatory or infectious process in the lungs that prevents him or her from being extubated.

CASE 106-4, QUESTION 2: What physiologic differences may need to be taken into account when developing a management strategy for J.B.?

There are developmental differences in the hemodynamic response to sepsis in newborns, children, and adults. Practitioners in the PICU may encounter all age ranges and thus must be familiar with the clinical differences seen between age groups because it may affect therapy. Adults and children have different adaptive responses that must be considered when selecting therapeutic management. Adolescent patients pose a unique challenge because they may present with either type of symptom. Among adult patients, the most common hemodynamic alterations include diminished systemic vascular resistance (SVR) and elevated CO. SVR is diminished because of decreased vascular responsiveness to catecholamines, alterations in α-adrenergic receptor signal transduction, and the elaboration of inducible nitric oxide synthase.

In general, adults with SS have myocardial dysfunction with a decreased ejection fraction; however, CO is preserved or increased through two compensatory mechanisms: tachycardia and reduced SVR.

Unlike SS in adults, pediatric SS is associated with severe hypovolemia, and children frequently respond well to aggressive fluid resuscitation. Pediatric patients demonstrate diverse hemodynamic profiles during fluid-refractory SS: 58% have low cardiac indexes (CIs) responsive to inotropic medications with or without vasodilators, 20% exhibit high CI and low SVR responsive to vasopressor therapy, and 22% present both vascular and cardiac dysfunctions necessitating the use of vasopressors and inotropic support.[26] Pediatric patients such as J.B. are different from adults with SS in that low CO, not low SVR, is associated with increased mortality. In fact, studies suggest that the majority of children showed some degree of cardiac dysfunction on presentation after fluid resuscitation.[14,19] Many require a change in their inotropic and vasopressor management, or the addition of another agent during the first hours of treatment, emphasizing that the hemodynamic status in children can change rapidly.[14,17–19]

SS in the neonatal patient differs from that seen in older children. The relative ability of infants and children to augment CO through increased HR, as seen in adults, is limited by their preexisting elevated HR, which precludes proportionate increases in HR without compromising diastolic filling time. In adults, ventricular dilation is a compensatory response used to maintain CO. However, the increased connective tissue content of the infant's heart and diminished content of actin and myosin limits the potential for acute ventricular dilation. Neonatal SS can be further complicated by the physiologic transition from fetal to neonatal circulation. Sepsis-induced acidosis and hypoxia can increase pulmonary vascular resistance and thus arterial pressure, thereby maintaining the patency of the ductus arteriosus (DA). This results in persistent pulmonary hypertension (PPHN) of the newborn and persistent fetal circulation. Neonatal SS with PPHN will increase the workload on the right ventricle, leading to right-ventricular failure, tricuspid

regurgitation, and hepatomegaly. Therefore, therapies directed at reversing right-ventricular failure by reducing pulmonary artery pressures are commonly needed in neonates with fluid-refractory SS and PPHN.

Based on her mottled dry skin, sluggish capillary refill, and decreased urination, it is evident that J.B. has inadequate perfusion. She should receive aggressive fluid resuscitation, beginning with a fluid bolus of 400 mL (20 mL/kg) balanced/buffered crystalloids IV administered over 5 minutes. She should be reassessed immediately after the bolus to evaluate perfusion status, as described previously. The 400-mL fluid bolus should be repeated until adequate perfusion has been established.

INITIAL MANAGEMENT OF PEDIATRIC SEPTIC SHOCK

Because the landmark study by Rivers in 2001 demonstrated a 33% reduction in mortality in adult patients with sepsis when they were aggressively treated with fluid resuscitation, blood transfusion, and inotropic therapy within 6 hours of admission, goal-directed therapy has been advocated for all patients who present in SS.[16] The components of early goal-directed therapy include respiratory support along with prompt resuscitation of poor perfusion through administration of IV fluids and appropriately targeted inotropic and vasopressor therapy, early empiric antimicrobial therapy, drainage of the infection whenever possible, and continuous monitoring of the patient's hemodynamic status.[14,16–20]

Case 106-4, Question 3: J.B. has received one bolus of LR in the pediatric emergency department but is still showing evidence of being hypoperfused. Her hemoglobin on admission to the PICU is 10 g/dL. Should she continue to receive traditional IV fluid replacement with LR or should other agents be considered to maximize perfusion and oxygenation?

There are no data to suggest a significant difference in survival rates in pediatric patients after resuscitation with colloids, including blood products, compared with crystalloid fluids.[27] The choice of fluid is less important than is the volume administered. Adequate volume is necessary to sustain cardiac preload, increase stroke volume, and improve oxygen delivery. Both crystalloids and colloids, specifically packed red blood cells (PRBCs), have equal effects on improving stroke volume. In addition, both restore tissue perfusion to the same degree if they are titrated to the same level of filling pressure.

Administration of blood products also differs among institutions. The optimal hemoglobin for infants and children in SS has not been established. The 2021 Adult SSC recommends using a restrictive transfusion strategy: maintaining hemoglobin of 7 g/dL to improve oxygen-carrying capacity.[28] However, administration of PRBC should not be guided by hemoglobin concentration alone. Assessment of the patients' overall clinical status with consideration of extenuating circumstances such as severe hypoxemia or acute hemorrhage is required. Anemia in sepsis has been associated with increased mortality, but so has the administration of blood products.[29] The 2020 SCCM Pediatric SSC guidelines recommend against transfusion of PRBC if the hemoglobin concentration is >7 g/dL in hemodynamically stabilized children with SS or other sepsis-associated organ dysfunction. Judgment should be used in those patients who are hemodynamically unstable.[15] At this time, there is no indication for administration of blood products to J.B. Fresh-frozen plasma may be infused to correct abnormal prothrombin time (PT) and partial thromboplastin time (PTT) values but should not be rapidly infused because of the risk of acute hypotensive effects caused by vasoactive kinins and high citrate concentration. There is no literature to suggest that 5% albumin administration improves outcome in regard to sepsis mortality. Albumin administration may be considered in patients who are hypoalbuminemic, but routine use of albumin is not recommended.[14,30]

As described previously for the management of hypovolemic shock, patients with SS should be reassessed for signs of improved perfusion using clinical criteria such as reduction in HR,

improvement of blood pressure, capillary refill, quality of pulses, and mental status with each fluid bolus. If the clinical signs of shock persist, another 20 mL/kg of balanced/buffered fluid should be administered, reaching, if necessary, 60 mL/kg within the first hour of treatment.[3,14,18] Some children with SS require as much as 200 mL/kg in the first hour.[17] Patients remaining in shock despite fluid resuscitation are given inotropic support to attain normal blood pressure for age and capillary refill time of <2 seconds. Every hour that goes by without implementing these therapies is associated with a 1.5-fold increased risk of mortality. Patients who do not respond rapidly to initial fluid boluses or those with insufficient physiologic reserve should be considered for invasive hemodynamic monitoring. Invasive monitoring of central venous pressure (CVP) is instituted to ensure that the satisfactory right-ventricular preload is present, typically using a goal of 10 to 12 mm Hg, and that oxygen-carrying capacity is optimized by PRBC transfusion to correct anemia to a goal hemoglobin concentration >7 g/dL.[14,18]

Up to 40% of a child's CO may be required to support the work of breathing during SS; therefore, in the presence of respiratory distress, elective intubation and mechanical ventilation can be used to allow redistribution of blood flow from respiratory muscles toward other vital organs. Intubation is not without adverse effects; it is imperative that patients receive adequate fluid resuscitation before intubation because the change from spontaneous breathing to positive-pressure ventilation will decrease the effective preload to the heart, further decreasing CO. Ventilation may reduce left-ventricular afterload that may be beneficial in patients with low CI and high SVR. In addition, it may provide an alternative method to alter acid–base balance. If sedatives and analgesics are used for intubation, choice of agents that do not cause further vasodilation is critical.

Although laboratory studies rarely affect the management of SS in the first hour of therapy, patients should have laboratory studies sent routinely assessing for hematologic abnormalities, metabolic derangements, or electrolyte abnormalities that may contribute to morbidity. A peripheral white blood count may aid in the choice of broad-spectrum antibiotics, and hemoglobin and platelet count will

help in assessing the need for early blood transfusion. A type and screen should be sent to the blood bank to prepare for any necessary transfusions. Electrolyte abnormalities are common in sepsis; recognition and treatment of metabolic abnormalities such as hypoglycemia and hypocalcemia will improve outcome. A disseminated intravascular coagulation panel, including PT, PTT, and fibrinogen, will aid in assessing the severity of the illness. If abnormalities exist, they may need to be corrected before performing invasive procedures. Lastly, an ABG or a venous blood gas will determine the adequacy of ventilation, oxygenation, and severity of acidemia.[18]

Unfortunately, clinical response to fluid resuscitation is a relatively insensitive indicator of the completeness of restoration of microvascular blood flow. Success of adequate fluid resuscitation can be guided by additional parameters: invasive blood pressure monitoring, CVP, measurement of mixed venous oxygen saturation (SvO_2), measurement of blood lactate, and urine output. An elevated serum lactate level suggests that tissue is inadequately perfused and undergoing anaerobic metabolism, even in patients who are not hypotensive. Because low CO is associated with increased O_2 extraction, SvO_2 can be used as an indirect indicator of whether CO is adequate to meet tissue metabolic demand. If tissue oxygen delivery is adequate, then SvO_2 should be >70%.[18] In the goal-directed study by Rivers, maintenance of SvO_2 was >70% by use of blood transfusion to a hemoglobin of 10 g/dL, and inotropic support to increase CO resulted in a 40% reduction in mortality compared with patients where only mean arterial pressure (MAP) and CVP were monitored.[16] de Oliveira et al[19] reproduced this finding in children with SS, reducing mortality from 39% to 12% when directing therapy to a goal SvO_2 saturation >70%.

CARDIOVASCULAR DRUG THERAPY

Pharmacologic support in children with SS must be individualized because different hemodynamic abnormalities exist in pediatric patients, and the primary hemodynamic abnormalities may change with time and progression of the patient's disease (**Table 106-10**). Twenty percent of children present with predominant vasodilatory shock, referred to as *warm* shock. This form of shock is associated with vasodilation and capillary leak, but normal or elevated CO. The patients have strong pulses, warm extremities, good capillary refill, and tachycardia. In warm shock, using a vasopressor such as dopamine, norepinephrine, phenylephrine, or vasopressin to promote vasoconstriction would provide the most benefit. Fifty-eight percent of children present with "cold shock" or a poor CO state. These patients have vasoconstriction, increased cardiac afterload, and a high SVR. This is clinically manifested as weak pulses, cool extremities, slow capillary refill, and hepatic and pulmonary congestion. Using an inotrope with or without a vasodilator would be most beneficial in cold shock (eg, dobutamine, epinephrine, or milrinone). Careful assessment of clinical response is critical because a combination of warm and cold shock, with a low SVR and poor CO, occurs in ~22% of children. SCCM previously recommended clinical assessment of children in SS to differentiate "warm" versus "cold" shock based on extremity temperature, capillary refill, pulse strength, and diastolic blood pressure and directing initial vasopressor choice on this diagnosis. However, several observational studies demonstrated very poor correlation of clinical assessment with CI and SVR when measured by advanced monitoring.[31–33] The newest SCCM Pediatric SSC guideline recommends a standard initial management of patients until more reliable assessment of the patient status is available.[14]

Table 106-10
Summary of Selected Vasoactive Agents

Agent	Dose Range	Peripheral Vascular Effects			Cardiac Effects
Vasopressors					
		α	β_1	β_2	
Dobutamine	2–20 μg/kg/minute	1+	3–4+	1–2+	Less chronotropy and arrhythmias at lower doses; chronotropic advantage compared with dopamine may not be apparent in neonates.
Dopamine	2–4 μg/kg/minute	0	0	0	Splanchnic and renal vasodilator, increasing doses create increasing α-effect.
	4–8 μg/kg/minute	0	1–2+	1+	
	>10 μg/kg/minute	2–4+	1–2+	2+	
Epinephrine	0.03–0.1 μg/kg/minute	2+	2–3+	2+	β_2 effects with lower doses
	0.2–0.5 μg/kg/minute	4+	2+	3+	
Norepinephrine	0.05–0.5 μg/kg/minute	4+	2+	0	Increases systemic resistance, moderate inotropy
Phenylephrine	0.05–0.5 μg/kg/minute	4+	0	0	Increases systemic resistance, moderate inotropy
Vasodilators					
Nitroprusside	0.5–8 μg/kg/minute	Donates nitric oxide to relax smooth muscles and dilate pulmonary and systemic vessels		Indirectly increases cardiac output by decreasing afterload	Reflex tachycardia
Nitroglycerine	0.5–10 μg/kg/minute	As a nitric oxide donor, may cause pulmonary vasodilation and enhance coronary vasoreactivity after aortic cross-clamping		Decreases preload; may decrease afterload, reduces myocardial work in relation to change in wall stress	Minimal
Miscellaneous Agents					
Milrinone	50 μg/kg load; then 0.25–1 μg/kg/minute	Systemic and pulmonary vasodilator		Diastolic relaxation (lusitropy)	Minimal tachycardia
Vasopressin	0.003–0.002 units/kg/minute *or* 18–120 mU/kg/hour	Potent vasoconstrictor		No direct effect	None known

CASE 106-4, QUESTION 4: Despite adequate fluid resuscitation, intubation, and mechanical ventilation, J.B.'s condition has continued to decline. During the past 30 minutes, her SBP has ranged between 72 and 79 mm Hg (normal for age, >84 mm Hg). What would be an appropriate next step for the management of J.B.'s shock?

Vasopressors are required in shock unresponsive to initial fluid resuscitation.[3,14,18] Previously, the PALS guideline recommended dopamine as the initial agent of choice.[18] However, the 2020 PALS update no longer recommends dopamine but agrees with the 2020 SCCM pediatric SSC guideline that recommends a catecholamine as the initial vasopressor of choice and only recommends dopamine if epinephrine or norepinephrine is unavailable.[34] Dopamine has direct and indirect effects on dopamine receptors, α-adrenergic receptors, and β-adrenergic receptors on both the heart and peripheral

vasculature. One of the mechanisms of dopamine action is enhancement of endogenous catecholamine release. In severe septic states, presynaptic vacuoles may be depleted of norepinephrine, which may explain why dopamine may have diminished activity. In addition, infants younger than age 6 months may not have developed their component of sympathetic innervations; therefore, they have reduced releasable stores of epinephrine.

Some studies have raised the concern of increased mortality with the use of dopamine. One possible explanation is the ability of dopamine to reduce the release of hormones from the anterior pituitary gland, such as prolactin, through stimulation of the dopamine D_2 receptor, thus reducing cell-mediated immunity and inhibition of thyrotropin-releasing hormone release, worsening impaired thyroid function known to occur in critical illness. Although, historically, dopamine was the drug of choice for initiating inotropic therapy in pediatric SS, the 2020 SCCM SSC guideline recommends epinephrine or norepinephrine as the initial vasopressor or choice.[14]

Epinephrine

Epinephrine is a direct agent that is naturally produced in the adrenal gland and is the principal stress hormone with widespread metabolic and hemodynamic effects. It possesses both inotropic and chronotropic effects. Epinephrine is a reasonable choice for the treatment of patients with low CO and poor peripheral perfusion because it increases HR and myocardial contractility. Depending on the dose administered, epinephrine may exert variable effects on SVR. At doses <0.3 μg/kg/minute, epinephrine exerts greater β_2-adrenergic receptor activation, resulting in vasodilation in skeletal muscle and cutaneous vascular beds, shunting blood flow away from the splanchnic circulation.[18] At higher doses, α_1-adrenergic receptor activation becomes more prominent and may increase SVR and HR. For patients with markedly elevated SVR, epinephrine (0.05–0.3 μg/kg/minute) may be administered simultaneously with a

vasodilator. Epinephrine increases glucogenesis and glycogenolysis, resulting in elevated serum blood glucose concentrations. Children receiving epinephrine infusions should have serum glucose monitored closely.

Norepinephrine

Norepinephrine is a direct agent and is naturally produced in the adrenal gland. It is a potent vasopressor that redirects blood flow away from skeletal muscle to the splanchnic circulation even in the presence of decreased CO. Norepinephrine has been used extensively to elevate SVR in adults and children with sepsis. If the patient's clinical state is characterized by low SVR (a wide pulse pressure with diastolic blood pressure less than one-half of the SBP), norepinephrine (0.05–0.3 µg/kg/minute) is recommended. Approximately 20% of children with volume-refractory SS have a low SVR. In children who are intubated and receiving sedatives or analgesics, the incidence of low SVR may be higher. The additional afterload imposed by norepinephrine may substantially compromise CO in patients with impaired contractility. In patients with both impaired or marginal CO and decreased SVR, it may be necessary to support myocardial contractility through the addition of an agent such as dobutamine.[14,18]

No studies directly compare epinephrine with norepinephrine. However, epinephrine has been compared to dopamine in two randomized controlled trials in children with fluid-refractory SS. In both clinical trials, epinephrine was associated with a lower risk of mortality and more organ failure–free days.[35,36]

J.B. should be started on epinephrine at a rate of 0.1 µg/kg/minute, with further titration of the dose in increments of 0.05 µg/kg/minute every 3 to 5 minutes until the goal of improved perfusion and/or a normal blood pressure for age is achieved.[3] There is no recommended maximum dose of epinephrine; however, the typical dose range is 0.05 to 0.3 µg/kg/minute. Ideally, vasopressors should be administered through central venous access rather than

through a peripheral IV; however, lack of central access should not prevent initiation of vasopressor therapy. Extravasation of these drugs from an infiltration of the IV may produce significant local tissue necrosis. Central access should be obtained as soon as possible.

Case 106-4, Question 5: J.B.'s epinephrine infusion has been steadily increased throughout the day. Her dose is currently at 0.3 µg/kg/minute, but she continues to have refractory hypotension with an SBP of 70 mm Hg. On physical examination, she is pale with cool, dry skin. Her hemoglobin remains at 10 g/dL. CVPs are now being measured and range from 6 to 9 mm Hg. What alternative to epinephrine should be considered for J.B.?

Catecholamine-resistant shock is diagnosed after titration of epinephrine or norepinephrine to 0.3 µg/kg/minute with the persistence of signs and symptoms of shock. Patients with catecholamine-resistant shock should be reassessed to evaluate fluid status and hemoglobin, with additional fluids or PRBCs given as needed to improve tissue oxygen. Measurement of CVP can be performed to assess intravascular volume status with the goal of achieving a CVP of 8 to 12 mm Hg, and SvO_2 can be used as a marker of CO (provided that the hemoglobin is within the normal range), along with the clinical examination. The SCCM pediatric SSC guideline recommends the addition of vasopressin or further titrating catecholamines in children with SS who require high-dose catecholamines.[14]

Vasopressin

Although not a recommendation in the 2020 PALS guidelines, vasopressin has been suggested as an alternative therapy for refractory cardiac arrest or hypotension due to a low SVR in children whose epinephrine infusion exceeds 1 µg/kg/minute.[3] Thus, the SCCM 2020 SSC recommendations to add vasopressin or to further titrate catecholamines with catecholamine-resistant shock. Vasopressin exerts its hemodynamic effects via the V_{1a} receptor,

promoting an increase in intracellular calcium in the peripheral vasculature, thus enhancing vasoconstriction and restoring systemic vascular tone. In a preliminary case series, vasopressin at a dose of 0.3 to 2 mU/kg/minute (18–120 mU/kg/hour) improved blood pressure and urine output in patients with catecholamine-refractory vasodilatory shock and allowed weaning of catecholamines once treatment was initiated.[37] In a more recent analysis conducted by the American Heart Association, however, vasopressin use was associated with a lower rate of return to spontaneous circulation.[38] More clinical studies with vasopressin in pediatric SS would allow for optimization of its use.[3,14,18]

Dobutamine

Dobutamine is a nonselective β_2-adrenergic agonist, which produces improved contractility, chronotropy, and some degree of lusitropy or improved myocardial relaxation. The β_2 activity can lead to peripheral vasodilation, and this must be considered before its use in a patient who may already be hypotensive. If hypotension does exist, it should be used in combination with other vasopressor therapies. Dobutamine should be considered in a patient who has signs and symptoms or laboratory values consistent with poor tissue perfusion but has an adequate blood pressure to tolerate some degree of vasodilation. It should be initiated at a rate of 2.5 µg/kg/minute and titrated in increments of 2.5 µg/kg/minute every 3 to 5 minutes to a maximum infusion rate of 20 µg/kg/minute.[3,18] Careful attention to the patient's blood pressure is critical. Improved perfusion, decreased lactate, and an increased SvO_2 will help determine appropriate dosing.

Vasodilators

Vasodilator medications are occasionally required in the treatment of pediatric patients who have sepsis with markedly elevated SVR and normal or decreased CO. Vasodilators decrease SVR and improve

CO by decreasing ventricular afterload. Nitroglycerin or nitroprusside may be used for this indication. They each have a short half-life; therefore, if hypotension occurs, it can be rapidly reversed by stopping the infusion. Both drugs can be infused at an initial rate of 0.5 μg/kg/minute and titrated in increments of 0.5 μg/kg/minute to a maximum infusion rate of 5 to 10 μg/kg/minute.[3] If nitroprusside is used, it is necessary to observe for sodium thiocyanate accumulation in the setting of renal failure, and cyanide toxicity with hepatic failure or with prolonged infusions (>72 hours) of >3 μg/kg/minute. If a patient has tolerated short-term infusions of either of these agents, milrinone may be considered as an alternative for long-term therapy. Milrinone is a phosphodiesterase type III (PDE III) inhibitor that produces its hemodynamic effects by inhibiting the degradation of cyclic adenosine monophosphate (AMP) in smooth muscle cells and cardiac myocytes. PDE III inhibitors work synergistically with catecholamines, which produce their hemodynamic effects by increasing the production of cyclic AMP. Milrinone, at a dose of 0.25 to 0.75 μg/kg/minute, is useful in the treatment of infants and children with diminished CO, impaired myocardial contractility, and decreased SVR.[13,39] The primary concern with milrinone is its relatively long half-life of 2 to 6 hours, which requires several hours for the patient to reach steady state. To achieve target serum concentrations more rapidly, a loading dose of 50 μg/kg may be administered for 10 to 30 minutes before the start of the infusion. Administration of a loading dose must be done with caution in children with sepsis and shock because it may precipitate hypotension, requiring volume infusion and/or vasopressor infusion. Administering the loading dose over several hours may avoid this adverse effect.

J.B. remains hypotensive despite adequate fluid administration and an epinephrine infusion at 0.3 μg/kg/min. After reassessing her laboratory parameters to determine whether additional fluid or blood products are needed, J.B. should be started on vasopressin at 18 mU/kg/hour. The dose may then be titrated upward in 10 to 20 mU /kg/hour increments every 3 to 5 minutes as needed to achieve the desired clinical response or to the usual maximum of 120 mU

μg/kg/hr. It would be acceptable to continue to increase the epinephrine infusion and consider vasopressin at a higher epinephrine infusion rate.

CORTICOSTEROID ADMINISTRATION IN PEDIATRIC SEPTIC SHOCK

CASE 106-4, QUESTION 6: J.B. is currently receiving epinephrine at an infusion rate of 0.35 μg/kg/minute, but she continues to have refractory hypotension with an SBP of 70 mm Hg. Is there a role for hydrocortisone replacement in J.B.? What would be the appropriate method for assessing adrenal insufficiency and the appropriate dose for replacement?

Although adjunctive corticosteroid therapy in patients in SS has not made a significant difference in outcome in all studies published to date, replacement may be of benefit in some patients.[40–42] In a recent study, 77% of children with SS admitted to two PICUs for a 6-month period exhibited adrenal insufficiency.[42] Owing to the limited evidence of their efficacy and safety in children, corticosteroids should be reserved for those with catecholamine-resistant shock, severe SS and purpura, children who have previously received steroid therapies for chronic illness, children with pituitary or adrenal abnormalities, and those who previously received etomidate.[5–7,13,40–42] The SCCM Pediatric SSC guideline no longer recommends assessment of serum cortisol to guide treatment.

Because excessive fluid resuscitation can lead to fluid overload, which has been associated with increased mortality in critically ill children,[43] medication therapies that can minimize their use should be considered. At least one pediatric trial examining adjunct corticosteroids for SS has concluded that their use may hasten the resolution of shock.[44] J.B. has catecholamine-resistant hypotension and has received a total of 80 mL/kg of fluid resuscitation; a trial of hydrocortisone is warranted. Published guidelines for hemodynamic support of pediatric and neonatal patients in SS recommend 0.5 to 1

mg/kg IV every 6 hours (with a maximum dose of 50 mg).[17] Using this regimen, J.B. should be treated with 10 to 20 mg IV every 6 hours. As an alternative, some clinicians use a regimen of a single 50-mg/m^2 loading dose, followed by the same dose (50 mg/m^2) divided into four doses and given every 6 hours.[14]

ADJUNCTIVE THERAPIES

Stress-Related Mucosal Bleeding

The use of prophylaxis to prevent stress-related mucosal bleeding, although common in adult patients in the ICU, is not as widely used in PICUs. Studies conducted to date have provided a wide range of gastrointestinal tract bleeding rates in children, ranging from 10% to 50%, with rates of clinically significant bleeding of ~1% to 4%.[45,46] Several investigators have identified thrombocytopenia, coagulopathy, organ failure, and mechanical ventilation as important risk factors for gastrointestinal bleeding, similar to studies conducted in adults. A recent systematic review suggested that critically ill pediatric patients may benefit from prophylaxis; however, the results were limited by the small number of controlled studies available.[46]

Thrombosis Prophylaxis

Patients admitted to the PICU can range from newborns to young adults. Unlike adults, there are no data on the use of subcutaneous heparin or low-molecular-weight heparins as prophylaxis to prevent deep vein thrombosis (DVT) in children. However, when children reach puberty, the hormone changes that take place appear to increase their risk of thrombosis to that of adults. Although no published guidelines or consensus papers exist to guide therapy at this time, all pubescent adolescents should be considered for DVT prophylaxis. Most cases of thrombosis in infants and young children are associated with long-term use of central venous catheters.

Unfortunately, a study evaluating low-dose heparin infused at 10 units/kg/hour did not prevent catheter-related thrombosis in infants after cardiac surgery.[47] It is important to note that the dose of heparin used in this study was less than the anticoagulant dose recommended for infants and children (15–25 units/kg/hour). At this time, the routine use of DVT prophylaxis in children remains controversial.

CONGENITAL HEART DISEASE

CASE 106-5

QUESTION 1: J.F. is a 3-week-old, 7.72-pound (3.5-kg) male who was seen by his physician with a history of poor feeding and increased work of breathing. On admission, he was mottled, and grunting, and had severe retractions. The physician referred him to the emergency department of the local children's hospital where his temperature was 105.44 °F (40.8 °C), HR was 200 beats/minute, respiratory rate was 80 breaths/minute, and oximetry saturation was between 60% and 70%; he had very poor peripheral perfusion. Blood gas analysis results were as follows:

pH, 6.96
P_{CO_2}, 35 mm Hg
Base deficit, 29 mmol/L

Chest radiography showed cardiomegaly and pulmonary edema. J.F. has presented with symptoms of both respiratory failure and shock. Based on his age, the severity of his hypoxemia, and evidence of cardiomegaly, CHD is suspected. Echocardiography reveals coarctation of the aorta.

What initial therapies are needed to stabilize J.F.?

With the neonate's first breath, changes in oxygen tension and a reduction in endogenous prostaglandin E_2 production stimulate closure of the DA, the connection between the pulmonary artery and aorta that allows shunting of blood to the aorta during fetal circulation. Functional closure of the DA typically occurs within the first 10 to 14 hours of life, but complete anatomic closure may not occur until age 2 to 3 weeks. Prematurity, acidosis, and hypoxia

prolong the time to closure. In infants with ductal-dependent CHD, closure of the DA results in inadequate delivery of oxygenated blood to the systemic circulation (**Table 106-11**). These infants will present just as any other patient in shock. The immediate goal in evaluating a cyanotic neonate is to differentiate between cardiac and noncardiac causes. The classic hyperoxia test is carried out by obtaining an ABG, then placing the patient on 100% oxygen for 10 minutes, and repeating the ABG. If the cause of cyanosis is pulmonary, the Pa_{O_2} should increase by 30 mm Hg, but if the cause is cardiac, there should be minimal improvement in the Pa_{O_2}. If the patient is too unstable, one could place a pulse oximeter and place the patient on 100% F_{IO_2}. With administration of oxygenation, there will typically be at least a 10% increase in oxygen saturation in neonates with pulmonary disease, but those with ductal-dependent CHD will have minimal or no improvement.

Table 106-11

Ductal-Dependent Congenital Heart Lesions

Lesions That Depend on Flow via the Ductus Arteriosus to Maintain Systemic Circulation
Hypoplastic left heart syndrome (HLHS)
Coarctation of the aorta
Critical aortic stenosis
Interrupted aortic arch
Total anomalous pulmonary venous return (TAPVR) with obstruction
Lesions That Depend on Flow via the Ductus Arteriosus to Maintain Pulmonary Circulation
Pulmonary atresia with intact ventricular septum
Critical pulmonic stenosis
Tricuspid atresia
Tetralogy of Fallot (TOF)
Epstein anomaly

Lesions That Depend on Flow via the Ductus Arteriosus to Maintain Systemic Circulation
Lesions That Depend on Flow via the Ductus Arteriosus to Maintain Adequate Mixing of the Pulmonary and Systemic Circulations
Truncus arteriosus
Transposition of the great vessels (TGV)
Total anomalous pulmonary venous return (TAPVR) without obstruction

If the neonate's oxygen saturation or Pa_{O_2} fails to improve and CHD is suspected, an infusion of alprostadil, prostaglandin E_1 (PGE_1), should be initiated at a rate of 0.05 to 0.1 µg/kg/minute.[48] Infusion of PGE_1 maintains patency of the DA and allows blood to reach the descending aorta, bypassing the cardiac defect. Apnea is a common adverse effect of PGE_1, occurring in 10% to 20% of patients, so age-appropriate equipment for intubation and mechanical ventilation should be immediately available before starting treatment and throughout therapy.[49] Within 10 to 15 minutes of starting an alprostadil infusion, there should be an improvement in the patient's oxygen saturation. The dose may then be titrated to optimize ductal flow and minimize dose-related adverse effects. The infusion is typically continued until corrective cardiac surgery can be performed. J.F. should receive fluid boluses as needed to correct his dehydration and will require intubation. In addition, he should be started on PGE_1 at a rate of 0.05 µg/kg/minute, with subsequent titration of the dose to open and maintain the DA until the time of surgery.

PEDIATRIC TRAUMATIC BRAIN INJURY

Among children, traumatic brain injury (TBI) is the leading cause of mortality and leads to significant morbidity among survivors. Each year, >280,000 children in the United States suffer a TBI requiring an emergency department visit, resulting in 16,070 hospitalizations in

2019 and 3000 deaths.[50] The most common mechanisms of injury differ by patient age. Children younger than 4 years old most often suffer injuries due to child abuse, falls, and motor vehicle collisions (MVCs). Child abuse, or nonaccidental trauma (NAT), sadly represents up to two-thirds of severe TBI in some series. Although it is difficult to obtain accurate data, in a population-based study from North Carolina, the incidence of TBI due to NAT in the first 2 years of life was 17 per 100,000 person-years.[51] According to the National Center on Shaken Baby Syndrome, this translates to ~1300 children per year in the United States who experience severe head trauma from child abuse. In school-aged children, those ages 5 to 12 years, pedestrian–MVC and bicycle-related injuries are among the more common causes of severe injuries. For adolescents, MVCs replace falls as the leading cause of all injuries, followed by assault and sports-related injuries.

CASE 106-6

Question 1: K.B. is an 8-week-old, 8.82-pound (4-kg) male who was brought to an urgent care clinic by his 17-year-old mother. She stated that he would not wake up for his usual 7:00 PM feeding that evening. He had been in his usual state of health that morning. She fed him his usual bottle, changed his diaper, and laid him down for a nap. She left him in the care of her 19-year-old boyfriend and went to work. At the clinic, the infant was floppy and unarousable. There were no bruises or other signs of injury, but the anterior fontanel was bulging. His pupils were 3 mm and responded sluggishly to light. When prompted, the boyfriend stated that K.B. fell off the couch early in the morning but only cried for a few minutes. After some comforting, he went back to playing. He fed well the remainder of the day and was taking his evening nap when the mother returned from work. The urgent care clinic suspected NAT and transferred K.B. to the closest hospital with pediatric critical care services.

What physiologic differences place K.B. at greater risk for severe TBI than does an older child? What risk factors or associations for NAT can you identify in this case?

The anatomic differences of the infant's brain render it more susceptible to certain types of injuries after head trauma.[52] Infants such as K.B. and young children have large, heavy heads. The head is unstable because of its relative size to the rest of the body. If an

infant or a young child falls a significant distance, is ejected during an MVC, or is thrown from a bicycle after colliding with an automobile, the head will tend to lead (ie, the infant or child will fly head first) and severe head injuries will occur when the head ultimately strikes the ground or another object. The infant's weak neck muscles also allow for greater movement when the head is acted on by acceleration/deceleration forces. The skull is thinner during infancy and early childhood, providing less protection for the brain and allowing forces to transfer more effectively across the shallow subarachnoid space. The base of the infant's skull is relatively flat, which also contributes to greater brain movement in response to acceleration/deceleration forces. In addition, the infant's brain has a higher water content (~88% vs 77% in an adult), which makes the brain softer and more prone to acceleration/deceleration injury. The water content is also inversely related to the myelination process, and the higher percentage of unmyelinated brain makes it more susceptible to sheer injuries. The infant brain is typically fully myelinated by age 1 year. As the result of these physiologic differences, there are differences in the pathology after pediatric TBI by age group. In infants and young children, diffuse injury, such as diffuse cerebral swelling, and subdural hematomas are more common than are focal injuries, such as contusions, that are typically seen in older children and adults. The typical pattern of hypoxic-ischemic injury in infants and young children after NAT is rarely seen in older children and adults who are victims of abuse.

Goldstein et al[53] have published risk factors for NAT based on data gathered from several earlier reports. They found that victims of inflicted head injury tended to be younger, more often from families of poorer socioeconomic backgrounds, and were more likely to have parents who were younger than age 18 years and who had never been married. In addition, a history inconsistent with physical findings was strongly associated with the presence of inflicted head injury. Additional risk factors reported as associated with NAT are alcohol or drug abuse, previous social service intervention, or a past history of child abuse, in combination with either retinal hemorrhages or an inconsistent history or physical examination. These

investigators found this combination was 100% predictive of child abuse in children admitted to a PICU. K.B. met many of these risk factors: He is young, has an unmarried parent who is younger than 18, and is from a low socioeconomic background. In addition, his injuries appear inconsistent with the history of falling from a couch. A fall of ~3 feet is required to cause significant head injury to an infant or a child; a standard couch is 18 inches from the floor.[54]

CASE 106-6, QUESTION 2: K.B. was transferred immediately to the emergency department at a local hospital. The O_2 saturation on room air was 100%, blood pressure 90/63 mm Hg, and HR 120 beats/minute. The initial Glasgow Coma Scale (GCS) score on presentation was 7, with 2 for eye opening in response to pain, 4 for withdrawing to pain, and 1 for no verbal response. What test or assessment tools are useful for evaluating the extent of K.B.'s injuries? Which are best for predicting his outcome?

The ability to evaluate the severity of TBI is essential to appropriately direct care, predict outcomes, and compare results to evaluate and improve patient care. Initial symptoms on presentation have been found to have little or no correlation with injury severity after TBI. The GCS is a widely accepted method in initially evaluating and characterizing patients with trauma and head injuries (**Table 106-12**). The scale is composed of visual, motor, and verbal components, with lower scores representing more serious injuries. The severity of TBI may be characterized as mild (GCS 13–15), moderate (GCS 9–12), or severe (GCS 3–8) on presentation; however, continued evaluation of GCS scores is the best way to track the patient's clinical progress. K.B.'s GCS of 7 on admission puts him in the category of severe TBI.

Table 106-12
Modified Glasgow Coma Scale

Eye Opening			
Score	*≥1 year*	*0–1 year*	
4	Opens eyes spontaneously	Opens eyes spontaneously	
3	Opens eyes to verbal command	Opens eyes to shout	
2	Opens eyes in response to pain	Opens eyes in response to pain	
1	No response	No response	
Best Motor Response			
Score	*≥1 year*	*0–1 year*	
6	Obeys command	N/A	
5	Localizes pain	Localizes pain	
4	Flexion withdrawal	Flexion withdrawal	
3	Flexion abnormal (decorticate)	Flexion abnormal (decorticate)	
2	Extension (decerebrate)	Extension (decerebrate)	
1	No response	No response	
Best Verbal Response			
Score	*>5 years*	*2–5 years*	*0–2 years*
5	Oriented and able to converse	Uses appropriate words	Cries appropriately
4	Disoriented and able to converse	Uses inappropriate words	Cries
3	Uses inappropriate words	Cries and/or screams	Cries and/or screams inappropriately
2	Makes incomprehensible sounds	Grunts	Grunts
1	No response	No response	No response

Source: Chung CY, Chen CL, Cheng PT, See LC, Tang SF, Wong AM. Critical score of Glasgow Coma Scale for pediatric traumatic brain injury. *Pediatr Neurol.* 2006;34:379–387.

The radiologic examination of choice for immediate assessment of a child with severe TBI is a noncontrast cerebral computed tomography (CT) scan. Most children with severe TBI undergo immediate CT imaging to delineate their injuries as soon as they have been fully assessed and sufficiently stabilized to permit safe transport to the radiology suite. If the brain injury does not need immediate surgical intervention, the patient's care is continued in the PICU with the implementation of therapies designed to minimize secondary brain injury. In a retrospective review of 309 children presenting with TBI, Chung et al[55] found that the GCS score was more useful in predicting survival among pediatric victims of TBI than were CT findings and the presence of injuries to other organ systems. In addition, they identified that a GCS score of <5, rather than a score of <8 as used in adults, was the threshold at which the patient was more likely to have a poor outcome. The authors also found that head CT findings of swelling or edema and subdural and

intracerebral hemorrhage were associated with worse outcomes than was subarachnoid or epidural hemorrhage.

Retinal hemorrhages are frequently, although not always, observed in inflicted head injury in infants and young children. These hemorrhages are the result of sheer forces disrupting vulnerable tissue interfaces. The vitreous body is adherent to the retina in early childhood; shaking can cause retinal hemorrhaging throughout multiple tissue layers, extending to the periphery of the retina. This pattern is unique to "shaken baby syndrome." Although useful for diagnosis, the ocular examination is often deferred initially when evaluating an infant or a child for TBI, because the medications used to facilitate funduscopy will preclude the use of pupillary reactivity as a tool to monitor evolving intracranial events.

According to the American Academy of Pediatrics guidelines on imaging for NAT, a skeletal survey is strongly recommended in all cases of suspected physical abuse in children younger than age 24 months.[56] A skeletal survey consists of films of the extremities, skull, and axial skeletal images. Follow-up radiographs of the ribs to assess for healing fractures not seen in the acute phase may be helpful 2 to 3 weeks after the skeletal survey. As with the eye examination, the skeletal survey is often delayed until the child is more stable.

CASE 106-6, QUESTION 3: After assessment by the emergency department physician, K.B. was intubated using rocuronium and pentobarbital, placed on an F_{IO_2} of 100% and sent for a CT scan. The CT reveals a subdural hematoma and cerebral swelling. On arrival to the PICU, K.B.'s vital signs are as follows:

Blood pressure, 85/58 mm Hg
HR, 125 beats/minute
Respiratory rate on the ventilator, 20 breaths/minute

Temperature was 98.42 °F (36.9 °C). What are the next goals for stabilization of K.B.?

The initial management of a child with a head injury should focus on the basics of resuscitation: assessing and securing the airway, ensuring adequate ventilation, and supporting circulation.[57] In

addition, the goals of treatment of TBI are directed toward protecting against secondary brain insults (SBIs) that can exacerbate neuronal damage and brain injury. SBIs are often the result of systemic hypotension, hypoxia, hypercarbia, anemia, and hyperglycemia. Aggressive treatment strategies are needed to prevent and/or treat these conditions to decrease morbidity and improve neurologic outcome after TBI in children. The criteria for tracheal intubation include hypoxemia not resolved with supplemental oxygen, apnea, hypercarbia ($PaCO_2$ > 45 mm Hg), a GCS score ≤8, a decrease in GCS score >3 compared with the initial score, cervical spine injury, loss of pharyngeal reflex, or any clinical evidence of herniation. K.B. was intubated in the emergency department based on his presenting GCS score of 7. All patients should be assumed to have a full stomach and cervical spine injury, so the intubation should be carried out using an RSI with appropriate short-acting sedatives and muscle relaxants (see Tables 106-3 and 106-4).

After intubation, K.B.'s ventilatory goals include 100% oxygen saturation, normocarbia (35–39 mm Hg), and no hyperventilation, as confirmed by ABGs, end-tidal CO_2 monitoring, and chest radiographs showing the tracheal tube in a good position. Unless he has signs or symptoms of herniation, prophylactic hyperventilation ($PaCO_2$ < 35 mm Hg) should be avoided.[57] Hyperventilation causes cerebral vasoconstriction, which decreases cerebral blood flow and subsequent blood volume. Although it will lower ICP, hyperventilation may result in ischemia. Furthermore, respiratory alkalosis caused by hyperventilation makes it more difficult to release oxygen to the brain, shifting the oxygen–hemoglobin curve to the left. Short-term use of hyperventilation, however, may be useful in preventing herniation while other medical therapies are implemented. In addition to mechanical ventilation, the head of the bed should be kept in the neutral position and jugular venous obstruction should be avoided to prevent ICP elevation. Elevation of the head of the bed to 30 degrees usually decreases ICP.

Assessment and reassessment of the patient's circulatory status, including central and peripheral pulse quality, capillary refill, HR, and

blood pressure, is critical. Hypotension after pediatric TBI is associated with increased morbidity and mortality.[57] Initial treatment of hypotension in the child with a head injury is similar to that described earlier for pediatric shock; however, the goal SBP in the patient with TBI is typically higher: ≥50th to 75th percentile for age, sex, and height. Systolic blood pressure <75th percentile has been associated with a fourfold increase in the risk factor for poor outcome after severe TBI, even when values were ≥90 mm Hg.[58] This suggests a possible benefit of a higher blood pressure target until ICP or cerebral perfusion pressure (CPP) monitoring is in place to guide therapy. As a result of the need for higher SBP, norepinephrine and phenylephrine, agents with greater vasopressor effects, are more frequently used in this patient population.[59]

The solution of choice for IV maintenance fluids in children with TBI is normal saline for children older than 1 year of age and 5% dextrose with normal saline for infants. Because hyperglycemia is known to worsen SBI, initial IV fluids for children should not contain dextrose. Infants are an exception because their low glycogen stores make them prone to hypoglycemia, especially with poor oral intake. Hypoglycemia can also worsen neurologic outcome and should be avoided. Frequent assessment of blood glucose either by point-of-care testing or on an ABG is recommended.

Case 106-6, Question 4: K.B. has been intubated and placed on mechanical ventilation with an ABG showing that he is maintaining goal parameters. He is receiving fentanyl at 1 µg/kg/hour and a dexmedetomidine infusion at 0.5 µg/kg/hour. The head of the bed is raised 30 degrees and his head is midline, supported by a head roll. K.B. has both a pulse oximeter and an end-tidal CO_2 monitor for continuous evaluation of his oxygenation and CO_2. Blood pressure is being maintained at the 75th percentile for age, height, and sex. What is the next step in monitoring head injury in K.B.?

Fever increases metabolic demands and is associated with worse outcomes after TBI. Treatment for K.B. should include 60 mg of acetaminophen (15 mg/kg) orally or rectally every 6 hours as needed and a cooling blanket when necessary. Ibuprofen should be avoided

because it may increase the risk of bleeding. Patients who are hypothermic on arrival should only be actively rewarmed if there is hemodynamic instability or bleeding thought to be exacerbated by hypothermia. Serum electrolytes and osmolarity should be monitored regularly in K.B., along with accurate assessment of urine output. This is important to identify the development of either syndrome of inappropriate antidiuretic hormone or diabetes insipidus. Both have been reported to occur after pediatric TBI.[57]

One of the most significant consequences of TBI is the development of intracranial hypertension. The presence of an open fontanel or sutures in an infant with severe TBI does not preclude the development of intracranial hypertension or negate the utility of ICP monitoring. ICP monitoring is recommended for any child presenting with a GCS of ≤8.[60] When possible, placement of a ventriculostomy catheter provides accurate pressure monitoring and allows for acute drainage of cerebrospinal fluid (CSF) for treatment of elevated ICP and assessment of CPP. The CPP value is calculated by subtracting the ICP from the MAP (Eq. 106-1):

$$\mathrm{CPP} = \mathrm{MAP} - \mathrm{ICP} \qquad \textbf{(Eq. 106-1)}$$

This value is important as an indication of blood flow and oxygen that reaches the brain. Maintaining CPP requires optimization of MAP with fluid therapy, and, if necessary, vasoactive drugs. In the case of ICP elevation, inotropic or vasopressor agents may be used to optimize CPP by increasing MAP, even to the point of relative systemic hypertension. In adults, a CPP of 60 to 70 mm Hg is usually targeted.

These recommendations are based on pediatric TBI studies showing that CPP values ranging from 40 to 70 mm Hg are associated with a favorable outcome and that a CPP <40 mm Hg is associated with poor outcomes.[60] Because infants and children normally have a lower MAP and ICP, the SCCM Pediatric Fundamental Critical Care Support course recommends the following CPP ranges: 40 to 50 mm Hg in infants, 50 to 60 mm Hg in children, and 60 to 70 mm Hg in adolescents. The 2019 Guidelines

for the Management of Pediatric Severe Traumatic Brain Injury, Third Edition, recommended maintaining a minimum CPP of 40 mm Hg, with a target between 40 and 50 mm Hg to ensure that the minimum of 40 mm Hg is not breached. There may be age-specific thresholds with infants at the lower and adolescents at or above the upper end of this range.[57] A recent study by Allen and colleagues that included 55 children ages 0 to 5 years, 65 patients ages 6 to 11 years, and 197 patients ages 12 to 17 years evaluated age-specific CPP values and clinical outcomes. They demonstrated a decreased survival in persons 18 years and older who experienced prolonged CPP below 50 or 60 mm Hg, 6 to 17 years below 50 mm Hg, and in patients 0 to 5 years below 40 mm Hg. This supports the hypothesis that CPP targets should be age specific.[61]

Case 106-6, Question 5: The neurosurgeon has placed a ventriculostomy in K.B., and his initial ICP is 25 mm Hg. His other vitals are as follows:

Blood pressure, 83/50 mm Hg
HR, 140 beats/minute
Temperature, 101.3 °F (38.5 °C)

His pulse oximeter still reads 100% and the end-tidal carbon dioxide ($ETCO_2$) monitor reads 35 mm Hg. Sedative infusions are unchanged: fentanyl 1 µg/kg/hour and dexmedetomidine 0.5 µg/kg/hour. The pediatric intensivist has placed a central line, and the CVP is 10 mm Hg. What is K.B.'s calculated CPP? What interventions are recommended to treat this ICP elevation?

Uncontrolled increased ICP is very deleterious and must be aggressively treated as soon as possible to reduce cerebral ischemia. In this setting, the goal of any therapy is to lower ICP enough to increase CPP and improve cerebral oxygenation. All initial treatments should be reassessed for efficacy, including treatment of fever, avoidance of jugular venous outflow tract obstruction, maintenance of normovolemia and normocarbia, and provision of sedation and analgesia. The latter is of considerable importance because anxiety and pain have been shown to increase ICP. K.B. appears to be euvolemic by CVP measurement, is normocapnic, and his O_2 saturation is 100%. He is febrile; however, measures should

be taken to treat the elevated temperature. Although he is receiving continuous sedation, additional bolus doses of sedatives should be given whenever needed. Because K.B. has an elevated CPP in spite of these initial therapies, the best option would be to drain CSF. This will provide an immediate, but transient, decrease in ICP. K.B. may have CSF drained until an ICP value of 15 mm Hg is reached; it should never be drained to 0 mm Hg because edema and diffuse brain swelling could cause an obstruction in the lateral ventricles. When a ventriculostomy is in place and CSF is frequently drained, it is important to replace the CSF drained with an equal amount of normal saline. Draining of large amounts of CSF without IV normal saline replacement is associated with the development of hypochloremic metabolic alkalosis. Drainage of CSF in K.B. will provide a CPP in the 40- to 50-mm Hg range. If the ICP increases again, two interventions are recommended, either the addition of a vasopressor to increase SBP or the institution of hyperosmolar therapy.

Hyperosmolar therapy may be useful in preventing the ICP from exceeding 20 mm Hg and in maintaining normal CPP. Although, historically, mannitol is commonly used in the management of increased ICP in pediatric TBI, no well-designed evidence-based studies have been published to support its use in pediatric TBI. Mannitol reduces ICP by reducing blood viscosity, which promotes reflex vasoconstriction of the arterioles by autoregulation, thus decreasing cerebral blood volume and ICP. This mechanism is rapid, but transient, lasting about 75 minutes and requiring an intact autoregulation. It also produces an osmotic effect by increasing serum osmolarity, causing the shift of water from the brain cell to the intravascular space. Although this effect is slower in onset (15–30 minutes), the osmotic effect lasts up to 6 hours. Mannitol is a potent osmotic diuretic; osmotic diuresis should be anticipated and fluid resuscitation available to avoid hemodynamic compromise. A Foley catheter is recommended in these patients for accurate measurement of urine output. Mannitol is excreted unchanged in the urine; serum osmolarity should be maintained <320 mOsm/L to avoid the development of mannitol-induced acute tubular necrosis.

Bolus hypertonic saline (3%) is recommended in pediatric patients with TBI having an ICP >20 mm Hg.[57] The main mechanism of action of hypertonic saline is an osmotic effect similar to that of mannitol. Hypertonic saline exhibits several other theoretic benefits such as restoration of normal cellular resting membrane potential and cell volume, inhibition of inflammation, stimulation of atrial natriuretic peptide release, and enhancement of CO.[57] The theoretic advantage of hypertonic saline over mannitol is that hypertonic saline can be administered in a patient who is hemodynamically unstable without the risk of a subsequent osmotic diuresis. Continuous infusions of 0.1 to 1 mL/kg/hour of hypertonic saline titrated to maintain an ICP <20 mm Hg have been used successfully in children.[62] Bolus doses of 2 to 5 mL/kg of 3% sodium chloride have been administered over 10 to 20 minutes. Serum osmolarity and serum sodium increase when this regimen is used, but sustained hypernatremia and hyperosmolarity appear to be generally well tolerated. Hypertonic saline has been administered with a serum osmolarity reaching 360 mOsm/L without adverse effects in pediatric patients. Another potential concern with the use of hypertonic saline is central pontine myelinolysis that has been reported with rapid changes in serum sodium. Currently, clinical trials have shown no evidence of demyelinating disorders. Bolus administration of 0.5 mL/kg of 23.4% sodium chloride (maximum: 30 mL) in patients with refractory ICP has been suggested. However, more evidence on its safety and efficacy in pediatric patients is needed. Regardless of which hypertonic saline regimen is utilized, it is recommended to avoid a sustained (>72 hour) serum sodium >170 Eq/L because it is associated with thrombocytopenia and anemia. Avoiding sustained serum sodium >160 mEq/L is suggested to avoid the complication of DVT.[57] Therefore, a target serum sodium of 150 to 160 mEq/L is reasonable.

To bring his ICP values down to the normal range (>20 mm Hg), K.B. may be given sodium chloride 3% at an IV dose of 8 to 20 mL (2–5 mL/kg) administered over 10 to 20 minutes. The effects of hypertonic saline on ICP should be evident within 15 minutes. This dose may be repeated every 2 to 4 hours as needed. If intermittent

hypertonic saline fails to bring his ICP down adequately, K.B. may be given a continuous infusion of hypertonic saline 3%, beginning at 0.1 mL/kg/hour or mannitol at a dose of 0.5 to 1 g/kg infused over 20 to 30 minutes. Dosing of either agent should be guided by regular assessment of serum electrolytes and osmolarity.

Case 106-6, Question 6: K.B. has been in the PICU for 24 hours. Initial treatment allowed K.B. to maintain a CPP of 50 mm Hg and an ICP <20 mm Hg for the majority of the day. He is receiving 3% sodium chloride combined with maintenance IV fluids, giving him a serum sodium of 166 mEq/L. Intermittent ICP spikes have responded to intermittent 4-g doses of mannitol; however, the most recent serum osmolarity is 330 mOs/L. What options remain to treat increased ICP in K.B.?

Two nonsurgical options are included in the TBI guideline: barbiturate coma and therapeutic hypothermia.[57] Barbiturates exert neuroprotective effects by reducing cerebral metabolism, lowering oxygen extraction and demand, and alternating vascular tone. Barbiturate serum levels poorly correlate with clinical efficacy; therefore, monitoring of electroencephalographic (EEG) patterns for burst suppression is recommended. Burst suppression also represents near-maximum reduction in cerebral metabolism and cerebral blood flow. A pentobarbital loading dose of 10 mg/kg/dose may be administered over 30 minutes, followed by a continuous infusion of 1 mg/kg/hour. Additional loading doses, in 5 mg/kg/dose increments, may be necessary to achieve burst suppression. The primary disadvantage of barbiturate coma is the risk of myocardial depression and hypotension. In addition, the long-term effect on neurologic outcome is unknown. The TBI guideline states that high-dose barbiturate therapy may be considered in patients who are hemodynamically stable with salvageable severe head injury and refractory intracranial hypertension.[57] The SCCM Pediatric TBI guideline recommends that when high-dose barbiturate therapy is used to treat refractory ICP, continuous arterial blood pressure monitoring and cardiovascular support to maintain adequate CPP

are required because cardiorespiratory instability is common among patients treated with barbiturate coma.

Posttraumatic hyperthermia is defined as a core body temperature >101.3 °F (38.5 °C), and hypothermia is defined as a temperature of <95 °F (35 °C). Although most clinicians agree that hyperthermia should be avoided in children with TBI, the role of hypothermia is unclear. Potential complications associated with hypothermia are increased bleeding risk, arrhythmias, and increased susceptibility to infection. A multicenter, international study of children with severe TBI randomly assigned to hypothermia therapy initiated within 8 hours of injury (90.5 °F [32.5 °C] for 24 hours) or to normothermia (98.6 °F [37 °C]) was recently published.[62] The study reported a worsening trend with hypothermia therapy: 31% of the patients in the hypothermia group had an unfavorable outcome, compared with 22% of the normothermia group. There were several methodologic problems with this study. Although the investigators screened patients within 8 hours, the mean time to initiation of cooling was 6.3 hours, with a range of 1.6 to 19.7 hours. In addition, the protocol included a rapid rewarming of 32.9 °F (0.5 °C) every 2 hours so that the patients were normothermic by a mean of 19 or 48 hours postinjury. They found that the ICP was significantly lower in the hypothermia group during the cooling period but that it was significantly higher than that the normothermic group during rewarming. Another trial conducted in Australia and New Zealand evaluated strict normothermia (temperature 96.8–98.6 °F [36–37 °C]) versus therapeutic hypothermia (temperature 89.6–91.4 °F [32–33 °C]).[63] Patients were enrolled within 6 hours of injury, and therapeutic hypothermia or strict normothermia was maintained for 72 hours. The rewarming rate was at a maximum of 32.9 °F (0.5 °C) every 3 hours or slower if needed to maintain normal CPP or ICP >20 mm Hg. Rewarming took a median of 21.5 hours (16–35 hours) and was without complications. However, there was no difference in pediatric cerebral performance category (PCPC) scores between the two groups at 12 months.[64] It is unclear whether therapeutic hypothermia is not efficacious because patients are not cooled soon enough (median time to target temperature = 9.3 hours) or owing to

the heterogeneous nature of TBI. The pediatric TBI guideline states that despite the lack of clinical data, hypothermia may be considered in the setting of refractory intracranial hypertension.[57] If hypothermia is used and rewarming is initiated, it should be carried out at a rate of 32.9 to 33.8 °F (0.5–1 °C) every 12 to 24 hours or slower to avoid complications.

Decompressive craniectomy, removal of a section of the skull to allow room for brain swelling without herniation, is another option for managing pediatric patients with TBI who fail to respond to standard therapies. A randomized trial of early decompressive craniectomy in children with TBI and sustained intracranial hypertension revealed that 54% of the patients treated surgically had a favorable outcome compared with only 14% of those treated medically.[65] Additional case series have confirmed that patients who receive a decompressive craniectomy have improved survival and neurologic outcomes compared with those undergoing medical management alone.[66] As with barbiturate coma and therapeutic hypothermia, decompressive craniectomy is not without risk. A recent study reported an increased risk of posttraumatic hydrocephalus, wound complications, and epilepsy in children with severe TBI.[67] Further studies are needed to establish the timing, efficacy, and safety of this management strategy. The pediatric TBI guideline states that decompressive craniectomy should be considered in pediatric patients with severe TBI with neurologic deterioration, herniation, or intracranial hypertension refractory to intensive medical management.

CASE 106-7

QUESTION 1: L.B. is a 39.68-pound (18-kg), 6-year-old child hit by a car while riding her bicycle. When emergency medical services arrived, they witnessed a 2-minute tonic–clonic seizure. GCS score at the scene was 11.

Should L.B. receive anticonvulsant medication after her TBI?

Posttraumatic seizures (PTSs) are classified as early (occurring within 7 days of injury) or late (occurring after 7 days). In the immediate period after severe TBI, seizures increase the brain

metabolic demands, increase ICP, and are associated with TBI. Therefore, it would be prudent to prevent PTSs in the period when the patient is at the highest risk for SBI. Infants and children are reported to have a greater risk of early PTS compared with adults. Children younger than age 2 years have almost a threefold greater risk of early PTS after TBI than do children between ages 2 and 12 years. In addition to age, a low GCS (8–11) score has been linked to an increased risk of early PTS. The pediatric TBI guideline states that prophylactic antiseizure therapy is suggested to reduce the occurrence rate of early PTS. No prophylactic anticonvulsant therapy is recommended to prevent late PTS.[57]

The majority of the published studies in children have used phenytoin for PTS prophylaxis. The SCCM TBI guideline stated there was insufficient evidence to recommend the use of levetiracetam over phenytoin for the prevention of PTS. Owing to the seizure witnessed at the scene, her young age, and her initial GCS score of 11, L.B. meets the criteria for prophylaxis. An appropriate regimen for L.B. would be phenytoin 45 mg given orally three times daily (7.5 mg/kg/day) for 7 days.

Geriatric Drug Use

Suzanne Dinsmore, Mary-Kathleen Grams, and Kristin M. Zimmerman

CORE PRINCIPLES		CHAPTER CASES
AGE-RELATED PHYSIOLOGIC, PHARMACOKINETIC, AND PHARMACODYNAMIC CHANGES		
1	Age-associated physiologic changes are associated with pharmacokinetic and pharmacodynamic alterations of drugs in older adults. Decline in drug metabolism and excretion and exaggerated response to drugs are important considerations in drug therapy of older adults.	**Case 107-1 (Questions 1–4)**
2	Adverse drug events are one of the most important problems associated with drug use in older adults.	**Case 107-2 (Question 1)**
DISEASE-SPECIFIC GERIATRIC DRUG THERAPY		
		Case 107-2 (Question

1	Older adults have multiple chronic conditions and take numerous medications. Disease-state education, awareness of potential adverse effects and drug interactions, consultation with health care providers, and behavioral modification are important steps to ensure medication safety.	**2)**
2	Pharmacologic treatments of heart failure (HF) in older adults include diuretics, β-blockers, angiotensin-converting enzyme (ACE) inhibitors, or angiotensin-receptor blockers (ARBs), with or without digoxin and spironolactone. Benefits should be weighed against risks based on the patient's concurrent conditions.	**Case 107-2 (Questions 3, 4)**
3	Statins are the drug of choice for treating hyperlipidemia in older adults. Combination with other agents is considered only if necessary and is based on concurrent disease states, potential adverse effects, and drug interactions.	**Case 107-2 (Questions 5, 6)**
4	First-line therapy for the prevention of coronary artery disease (CAD) includes acetylsalicylic acid (ASA) and β-blockers. Other agents are considered based on concomitant diseases and relative indications.	**Case 107-2 (Question 7)**
5	Hypertension (HTN) should be treated in older adults according to the	**Case 107-2 (Question 8)**

	guidelines, and monitoring is essential to prevent excessively low blood pressure (BP), bradycardia, and orthostatic hypotension.	
6	The glycated hemoglobin ($HgbA_{1c}$) goal may be higher or relaxed in older adults who have episodes of hypoglycemia with standard goals. Pharmacologic therapies for diabetes are recommended based on the level of hyperglycemia and relative contraindications.	**Case 107-2 (Question 9)**
7	Depression is a common psychiatric disorder in older adults, often presenting with atypical symptoms. Selective serotonin reuptake inhibitors (SSRIs) are generally better tolerated than other agents and are considered a first-line therapy.	**Case 107-3 (Questions 1, 2)**
8	Asthma is a significant source of morbidity in older adults. The management of asthma in older adults does not differ significantly from that for younger individuals. However, coexisting chronic medical conditions, exaggerated systemic adverse drug reactions, and dexterity concerns must be considered when managing drug therapy for asthma in the older adult.	**Case 107-4 (Questions 1, 2)**
9	Pneumonia is the leading infectious cause of mortality in older adults, who typically presents with atypical	**Case 107-4 (Questions 3–5)**

	symptoms of lower respiratory infection. Influenza and pneumococcal vaccinations are beneficial in the prevention of pneumonia in the older population.	
10	Urinary tract infections (UTIs) are the most common bacterial infection in older adults. Oral antibiotics are appropriate for most older patients with symptomatic infection.	**Case 107-5 (Questions 1, 2)**
11	Arthritis is the most common cause of disability in older adults, and there are several analgesic agents available for the management of osteoarthritis. Safe and appropriate use of these analgesic medications is important because older adults are at increased risk of adverse drug reactions.	**Case 107-6 (Questions 1, 2)**
LONG-TERM CARE FACILITIES		
1	Federally mandated responsibilities of pharmacists in long-term care facilities (LTCFs) include monthly medication regimen review (MRR) for appropriateness of drug therapy. Provision of pharmaceutical care in LTCFs helps minimize medication errors, adverse drug reactions, and inappropriate prescribing.	**Case 107-7 (Questions 1, 2)**

INTRODUCTION

Demographic changes and medical progress in the United States over the past half of the 20th century have created the need for imperatives to improve our knowledge about the health care and drug therapy of older adults. The Federal Interagency Forum on Aging-Related Statistics is made up of multiple federal agencies that came together in 1986 to provide information on the health, finances, and well-being of older Americans in the United States.[1] Along with the National Institute of Aging, National Center for Health Statistics, and the Census Bureau, the latest report compiles information from over 16 national data sources and separates data into 41 indicators in the areas of population, economics, health status, health risks and behaviors, and health care and environment, of the older population. The U.S. Department of Health and Human Services published the "2019 Profile in Older Americans" in May 2020.[2] Both reports include valuable information that describe the older population (**Table 107-1**).

Table 107-1

2019 Profile of Older Americans

Current Facts About Older Americans[1,2]
▪ The older population, persons age 65 years and older, numbered 52.4 million in 2018, representing 16% of the U.S. population. This is a 35% increase from 2008.
▪ More than one in every seven Americans is considered an older adult.
▪ There are 29.1 older adult females and 23.3 million older adult males.
▪ The older population is getting even older. The 85 and older age group grew from just over 122,362 in 1900 to 6.5 million in 2018.
▪ The average life expectancy for those reaching age 65 is 85.7 years for females and 83.1 years for males.
▪ The centenarian population or those age 100 years and older accounted for 0.2% of the age 65 and older population in 2018.
▪ The most common and chronic health conditions among all persons age 65 years and older are heart disease, diagnosed and undiagnosed diabetes, cancer, stroke, and arthritis.
▪ Among all persons age 65 years and older, the leading causes of death are heart disease, cancer, chronic lower respiratory diseases, stroke, Alzheimer disease, diabetes, unintentional injuries, and influenza and pneumonia.

The Older Population Is Growing

- Thirty-six percent of the “baby boomer” generation are age 65 years and older.
- The population of those age 65 years and older is expected to increase to 94.7 million by 2060.
- The very old, those age 85 years and older are expected to double from 6.5 million in 2018 to 14.4 million in 2040.

Sources: Adapted from the Administration on Aging, Administration for Community Living, U.S. Department of Health and Human Services. *2019 Profile of Older Americans*. 2020:26; Federal Interagency Forum on Aging-Related Statistics. *Older Americans 2016: Key Indicators of Well-Being*. 2016.

The term “older adult” describes those age 65 years and older; and “oldest-old” describes those age 85 years and older. The oldest-old will have a significant impact on the health care system because the number of people in this group is expected to double from 6.5 million in 2018 to 14.4 million in 2040.[2]

Older adults often have multiple chronic conditions, higher prescription drug costs, and higher out-of-pocket health care expenditures and account for more overnight hospital stays than younger adults. Many older adults live at home and may receive personal assistances with one or more activities of daily living (ADLs), including bathing, eating, and dressing, or instrumental activities of daily living (IADLs), including preparing meals, washing clothes, shopping, paying bills, and taking medication. Often, informal care from children and other relatives is a large reason disabled older adults can continue to live in the community. Thus, it is important to include the caregiver in the counseling and monitoring of daily activities when feasible. An increase in this informal assistance and the reliance on others to perform ADLs and IADLs leads to a loss of independence and the inability of older adults to remain living at home or alone in the community. Approximately 1.2 million U.S. residents age 65 years and older reside in long-term care facilities (LTCFs). The percentage of those living in nursing homes increases with age (1% for age 65–74; 2% for age 75–84; 7% for age >85).

Health care for older adults in an institutional setting is largely based on a prospective reimbursement system, where payment for services is based on a fixed amount.[3] Managed-care practices aim to minimize high-cost hospitalizations by shifting care to lower cost alternatives, such as home health care, assisted living, and hospice care. The escalating costs and affordability of medications are a national concern, especially in the Medicare population. The Medicare Prescription Drug Improvement and Modernization Act of 2003 provided voluntary prescription drug insurance benefits, known as Medicare Part D, to improve older adults' access to prescription drugs.[4] The implementation of Medicare Part D is associated with an increase in drug use in older adults owing to accessibility and a decrease in patient out-of-pocket costs.[5]

AGE-RELATED PHYSIOLOGIC, PHARMACOKINETIC, AND PHARMACODYNAMIC CHANGES

Physiologic changes that are seen with aging are progressive and occur gradually over a lifetime, rather than abruptly at any given age.[6] These changes may lead to decreases in the function of tissues and organs and the ability of each organ system to maintain homeostasis: a phenomenon often called "homeostenosis."[7] The impaired ability to recover from drug-induced insults may increase the risk of drug-related problems in older adults. Homeostatic mechanisms in the cardiovascular and nervous systems are less efficient; drug metabolism, excretion, body tissue composition, drug volume of distribution, and drug receptor sensitivity may change or be altered. Age-related physiologic changes may result in pharmacokinetic and pharmacodynamic changes and should be considered when selecting and evaluating drug therapy.

Absorption

The absorption of some drugs administered by the extravascular route may be altered by age-related physiologic changes, unlike drugs administered by the intravascular route that are considered to have 100% bioavailability.[8] In the gastrointestinal (GI) tract, a decrease in intestinal blood flow, increase in gastric pH, delayed gastric emptying, and decreased GI motility occur with aging. Increased gastric pH due to aging alone is thought to have a minimal effect on absorption and be rarely clinically significant. However, the use of H_2-receptor antagonists and proton-pump inhibitors combined with gastric pH changes may affect drugs that require an acidic environment for absorption, such as iron, itraconazole, and ketoconazole. In general, the rate of absorption is slower or unaltered in older patients, and the extent of absorption by the oral route is similar as compared to young adults.

The transdermal administration of drugs is a convenient route of administration and used for several medications prescribed to older adults.[9] Changes in skin seen with aging such as decreased elasticity, thinning of the epidermis, dryness, and decreased sebaceous gland activity may affect drug absorption. Care should be taken to adjust doses and monitor to prevent potential adverse effects.[10]

Lipophilic drugs (eg, estradiol) appear to be less affected by aging skin and are easily dissolved, whereas hydrophilic compounds may not dissolve as readily on aging skin.

CASE 107-1

QUESTION 1: M.G. is a 75-year-old female, 64 inches (162.56 cm), 120 pounds (54.43 kg), with a serum creatinine (SCr) concentration of 1.9 mg/dL. She has an acute exacerbation of heart failure (HF) and is given furosemide 40 mg orally (po), but this produces little increase in urine output or resolution of her symptoms.

What would explain M.G.'s lack of response to furosemide, and how might the desired response to furosemide be achieved?

The extent of furosemide absorption is not changed in older patients, but the rate of absorption is slowed. This results in a

diminished efficacy of the drug because active secretion into the urine (rate of entry) must reach the steep portion of the sigmoid dose–response curve for maximal effect of the drug.[11,12] A higher concentration is needed to achieve the desired effect.

M.G. should be given a 40-mg dose of furosemide intravenously (IV) to bypass the problem of decreased rate of absorption by the oral route. High-sodium intake or concurrent use of nonsteroidal anti-inflammatory drugs (NSAIDs) may also decrease the effectiveness of furosemide. Further increases in dose of furosemide may be necessary, with consideration of a continuous infusion in patients with severe chronic renal insufficiency (see Chapter 28, Chronic Kidney Disease).

Distribution

There are a number of age-related changes that may affect the distribution of drugs in the body.[8,9] Total body water and lean body mass both decline with age by 10% to 15%, and total body fat increases by 20% to 40%.[13] Thus, the volume of distribution (V_d) of drugs that are distributed primarily in body water or lean body mass (eg, lithium, digoxin) is decreased in older adults, and unadjusted dosing may result in higher blood levels. Conversely, the V_d of highly lipid-soluble drugs, such as long-acting benzodiazepines (eg, diazepam), may be increased, thereby delaying maximal effects or leading to accumulation with continued use.[9]

Serum albumin concentrations were found to progressively decrease for each decade beyond age 40 years, reaching a mean of 3.58 g/dL in those older than 80 years, and this may reduce protein binding.[14] Changes in protein binding due to aging alone are thought to be only clinically significant with drugs that are highly extracted, are highly protein bound, have a narrow therapeutic index, have a small volume of distribution, and those given IV.[13] Other factors in older patients that may also affect binding include protein concentration, disease states, coadministration of other drugs, and nutritional status.

Altered Protein Binding

Case 107-1, Question 2: M.G. is brought to the emergency department (ED) for evaluation of a "shaking spell." In the ED, another "spell" is observed, starting with shaking of the left arm and progressing into a generalized tonic–clonic seizure. A loading dose of phenytoin 1000 mg is given IV over 30 minutes. M.G. is admitted to the neurology unit for further evaluation and given phenytoin 300 mg po at bedtime. Is the phenytoin regimen appropriate for M.G.? What laboratory tests should be ordered, and how often should these be monitored?

M.G. received a phenytoin loading dose of 17 mg/kg (adult dose 15–20 mg/kg) and is receiving the usual oral daily maintenance dose.[15] Monitoring parameters include a serum sodium concentration to rule out a hyponatremia-induced seizure. Because phenytoin is 90% protein bound, a serum albumin concentration should be drawn. In patients with hypoalbuminemia or renal impairment, free (unbound) phenytoin levels should be monitored. A serum phenytoin concentration at discharge to determine whether the desired therapeutic serum concentration has been achieved is also recommended. A follow-up, steady-state serum phenytoin concentration should be obtained in 10 to 14 days to evaluate the current dose and to determine whether dose adjustments are needed. The serum phenytoin concentration should be monitored periodically thereafter and whenever an adverse drug reaction or seizure occurs.

Case 107-1, Question 3: M.G. returns for a follow-up appointment 2 weeks later after having labs drawn. Serum albumin concentration is 2.2 g/dL, sodium 140 mEq/L, and serum phenytoin 15 µg/mL. M.G. has drowsiness and a wide-based, unsteady gait. What is the most likely cause of her symptoms?

Although the serum phenytoin is within the therapeutic range (10–20 µg/mL), phenytoin is highly protein bound, and in the presence of low albumin, free phenytoin concentrations could be higher. A

corrected phenytoin level can be calculated using the following equation:

$$\text{Total phenytoin concentration} = \text{Total phenytoin measured} / [(0.2 \times \text{Serum albumin g/dL}) + 0.1]$$

(Eq. 107-1)

This would produce an equivalent phenytoin concentration of 27 μg/mL, explaining M.G.'s symptoms (assuming her serum phenytoin concentration is at steady state). In M.G.'s case, free phenytoin (unbound phenytoin) concentration monitoring would be appropriate, if available, and her dosage should be adjusted accordingly.[15],[16]

Metabolism

M.G.'s phenytoin metabolism may be affected by factors known to influence hepatic drug metabolism, including disease states, concurrent drug use, nutritional status, environmental compounds, genetic differences, sex, liver mass, and blood flow. Liver mass decreases by ~20% to 30% with age, and hepatic blood flow decreases by ~20% to 50%.[13] Compounds undergoing phase I metabolism (reduction, oxidation, hydroxylation, demethylation) have a decreased or unchanged clearance, whereas compounds metabolized by phase II processes (conjugation, acetylation, sulfonation, glucuronidation) have no change in clearance with age.[8] Drugs with high hepatic-extraction ratios, such as the nitrates, barbiturates, lidocaine, and propranolol, may have reduced hepatic metabolism in older adults.[13] Some angiotensin-converting enzyme (ACE) inhibitors are prodrugs and need to be activated by the liver, and bioavailability may be decreased in older adults, especially when hepatic disease is present.[17]

Excretion

In older adults, changes in aging kidneys include a decrease in renal mass by 20% to 30%, decrease in renal blood flow, and decrease in tubular secretion.[9] After age 30 years, glomerular filtration rate (GFR) is estimated to decline 8 mL/minute every 10 years, although not all older adults have decreased renal function. Increases in sclerotic glomeruli and decreases in functioning glomeruli may contribute to a decline in GFR.[12]

The plasma half-life is prolonged for a number of renally excreted drugs in "healthy" older adults, and the highest risk drugs are those that depend entirely on the kidney for elimination. Examples of drugs that should be avoided or dose reduced in older adults due to reduced kidney function are listed in **Table 107-2**.

Table 107-2

Drugs Highly Dependent on Renal Function for Elimination

Acetazolamide	Dofetilide	Nadolol
Acyclovir	Duloxetine	Nitrofurantoin
Allopurinol	Edoxaban	Nizatidine
Amantadine	Enalapril	Penicillins (most)
Amiloride	Enoxaparin	Phenazopyridine
Aminoglycosides	Enoxaparin	Pregabalin
Amphotericin B	Famotidine	Pregabalin
Apixaban	Fluconazole	Probenecid
Atenolol	Fluoroquinolones (most)	Procainamide
Aztreonam	Fondaparinux	Pyridostigmine
Captopril	Furosemide	Ranitidine
Cephalosporins (most)	Gabapentin	Rivaroxaban
Cimetidine	Imipenem	Spironolactone
Ciprofloxacin	Levetiracetam	Thiazides
Clonidine	Lisinopril	Tramadol
Colchicine	Lithium	Triamterene
Dabigatran	Methotrexate	Trimethoprim/sulfamethoxazole

Digoxin	Metoclopramide	Vancomycin

This list does not include all drugs highly dependent on renal function for elimination.

Sources: Adapted from the 2019 American Geriatrics Society Beers Criteria® Update Expert Panel. American Geriatrics Society 2019 updated Beers Criteria for potentially inappropriate medication use in older adults. *J Am Geriatr Soc*. 2019;67(4):674–694. doi:10.1111/jgs.15767; Arnoff GR, Bennett WM, Berns JS, et al, eds. *Drug Prescribing in Renal Failure: Dosing Guidelines for Adults*. 5th ed. American College of Physicians; 2007.

GFR is the most prevalent measurement that is used to evaluate overall renal function and to diagnose kidney disease, using markers that are renally excreted such as creatinine.[18] These markers are measured by collecting urine over a 6- to 24-hour period and drawing blood before or after. Because timed urine and serum collections may not always be possible or accurate in older adults owing to inconvenience, or incomplete collection in those with incontinence, several equations are used to estimate creatinine clearance (CrCl).[19],[20] Whereas GFR is used to diagnose and stage kidney disease, equations that estimate CrCl are used to guide practitioners in drug dosing. The Cockcroft–Gault equation is commonly used for most drug dosing; however, controversies exist with regard to using actual or ideal weight and using correction factors in the calculation. The use of lean body weight in the equation may reflect SCr production more accurately because creatinine is produced in muscle mass, which is decreased in older patients. The Cockcroft–Gault equation depends on SCr concentration and tubular secretion of creatinine, which may result in an overestimation of renal function in patients with obesity.

Case 107-1, Question 4: For renally cleared drugs that require dosage adjustment for M.G., is the Cockcroft–Gault equation an appropriate tool to estimate renal function?

Cockcroft and Gault

$$eCrCl = (140 - age) \times \text{weight in kg} / (72 \times SCr) \times 0.85 \text{ in females} \quad \text{(Eq. 107-2)}$$

M.G. is 75 years old, weighs 120 pounds (54.43 kg), and her SCr is 1.9 mg/dL. Using the Cockcroft–Gault equation, her estimated CrCl is 22 mL/minute. The equation was derived from a predominantly male veteran population who had a single measured 24-hour CrCl, and a correction factor of 0.85 is used in female patients.[20]

M.G. is not underweight or obese, so the Cockcroft–Gault equation is an appropriate tool to estimate CrCl for drug dosing and remains the most common method to determine dosing of renally cleared drugs. Other assessments of renal function, including urine output, should be considered when assessing drug dosage adjustments in older individuals such as M.G., along with close monitoring for adverse drug reactions.

Table 107-3 provides a composite picture of the age-related physiologic changes, disease states, and pharmacologic factors that affect pharmacokinetic processes in older adults.

Table 107-3
Changes Affecting Pharmacokinetic Parameters

Parameter	Physiologic Changes	Disease States	Pharmacologic Factors
Absorption (bioavailability, first-pass metabolism)	Gastric pH Absorptive surface Splanchnic blood flow GI motility Gastric emptying rate	Achlorhydria, diarrhea, gastrectomy, malabsorptive syndromes, pancreatitis	Drug interactions, antacids, anticholinergics, cholestyramine, food
Distribution	Cardiac output TBW Lean body mass Serum albumin α_1-Acid glycoprotein Body fat Altered relative tissue perfusion	HF, dehydration, edema, ascites, hepatic failure, malnutrition, renal failure	Drug interactions, protein-binding displacement
Metabolism	Hepatic mass Enzyme activity Hepatic blood flow	HF, fever, hepatic failure, malignancy, malnutrition, thyroid disease, viral infection, or immunization	Dietary makeup, drug interactions, insecticides, alcohol, smoking, induction of metabolism, inhibition of metabolism
Excretion	Renal blood flow GFR Tubular secretion Renal mass	Hypovolemia, renal insufficiency	Drug interactions

GFR, glomerular filtration rate; GI, gastrointestinal; HF, heart failure; TBW, total body water.

PHARMACODYNAMIC CHANGES

Pharmacodynamics refers to the effect of a medication at its receptor site, or site of action, and is largely determined by drug concentration and its ability to bind at the receptor site.[13] Aging can affect the number of receptors available and their affinity to medications. Together, comorbidities, pharmacokinetic changes, and pharmacodynamic changes make an individual drug response in an older adult largely unpredictable. Because older adults can be sensitive to the effects of medication, care should be taken to avoid unwanted adverse effects when starting or stopping medications.

The ability to preserve homeostasis decreases with aging, which results in a decrease in functional reserve and a decreased ability to respond in times of physiologic stress. Cardiovascular changes during aging along with an impaired baroreceptor response increase the prevalence of orthostatic hypotension in older adults.[13,21] Prevalence ranges from ~6% in healthy older adults and up to 60% in hospitalized older adults.[22] Orthostatic hypotension is associated with the use of α-blockers, β-blockers, thiazide diuretics, and central sympathomimetics when used to treat hypertension (HTN). This may lead to an increased risk of falls in older adults.

Certain medications, such as digoxin, or classes of medications, such as antiarrhythmics, diuretics, narcotics, anticonvulsants, psychotropics, and antidepressants, can lead to gait disturbances, contribute to drug-induced falls, and lead to decreased mobility.[23] **Table 107-4** reviews medications commonly associated with adverse drug reactions that may contribute to gait changes and falls in older adults.[22–24]

Table 107-4
Medications Associated With Adverse Drug Reactions That May Contribute to Gait Changes and Falls in Older Adults

Medication Class	Adverse Drug Reaction
Tricyclic antidepressants	Orthostatic hypotension, tremor, cardiac

(TCAs)	arrhythmias, sedation
Benzodiazepines and sedative hypnotics	Sedation, weakness, coordination, confusion
Opiate analgesics	Sedation, coordination, confusion
Antipsychotics	Orthostatic hypotension, sedation, extrapyramidal effects
Antihypertensives	Orthostatic hypotension
β-Adrenergic blockers	Ability to respond to workload (dose needed may increase risk)

Blood–Brain Barrier

The function and integrity of the interface between the brain and the body, the blood–brain barrier, may decline as a result of aging, disease, or ischemic injury.[25] An exaggerated response and increased sensitivity to some drugs that effect the central nervous system (CNS) may be seen as a result of changes in permeability of the blood–brain barrier and changes in receptor sensitivity in older adults.[26] Normal aging involves a reduction in cerebral blood flow and oxygen consumption and increased cerebrovascular resistance. Drugs with anticholinergic properties are associated with memory loss, confusion, cognitive impairments, and functional decline in older patients. Several examples of therapeutic classes with anticholinergic properties are listed in **Table 107-5**.

Table 107-5
Medication With Anticholinergic Properties

Therapeutic Class	Example

Therapeutic Class	Example
Antimuscarinics	Darifenacin Fesoterodine Flavoxate Oxybutynin Solifenacin Tolterodine Trospium
Antispasmodic	Atropine[a] Clidinium–chlordiazepoxide Dicyclomine Homatropine[a] Hyoscyamine Propantheline Scopolamine[a]
Antiparkinson	Benztropine Trihexyphenidyl
Antihistamine	Brompheniramine Chlorpheniramine Clemastine Dimenhydrinate Diphenhydramine Doxylamine Hydroxyzine HCl Meclizine
Antidepressant	Amitriptyline Clomipramine Desipramine Doxepin (>6 mg) Imipramine Nortriptyline Paroxetine Trimipramine
Antiarrhythmic	Disopyramide Quinidine
Antipsychotic	Clozapine Olanzapine Perphenazine Thioridazine Trifluoperazine

Therapeutic Class	Example
Hypnotic	Hydroxyzine pamoate
Skeletal muscle relaxant	Cyclobenzaprine Orphenadrine

This chart does not include all anticholinergic drugs that may cause confusion in older adults.

[a]Does not include ophthalmic.

Source: Adapted from the 2019 American Geriatrics Society Beers Criteria® Update Expert Panel. Anticholinergic drugs and negative outcomes in the older population: from biological plausibility to clinical evidence. *Aging Clin Exp Res*. 2016;28(1): 25–35. doi:10.1007/s40520-015-0359-7.

Both central responsiveness and peripheral responsiveness of adrenergic receptors decline with aging.[27] Monoamine oxidase activity increases with normal aging, and this is reflected by a decline in norepinephrine and dopamine levels in aging brains.[28,29] The decline in CNS dopamine synthesis is associated with increased sensitivity to dopamine-blocking agents (eg, antipsychotics). Because neurologic and biochemical reserves are reduced as a normal consequence of aging, iatrogenic behavioral disorders are relatively common in older adults, and drugs are one of the most common causes of sudden, unexplained mental impairment in the older adult.

PROBLEMS ASSOCIATED WITH DRUG USE IN OLDER ADULTS

Polypharmacy

Over half of all older adults carry three or more chronic diseases. This multimorbidity is associated with increased morbidity, mortality,

functional decline, health resource use, and multiple medication use.[30]

Multiple medication use is often synonymous with polypharmacy. *Polypharmacy*, however, can be variably defined as the use of more than one medication, as more than a specific or numeric threshold of medications (eg, five or more), or as “excessive” or “unnecessary” use of medication.[31] Polypharmacy is associated with multiple adverse health outcomes, including increased drug-related adverse events, functional impairment, institutionalization, hospitalization, health care costs, and mortality.[32] A thorough medication review is essential to identifying and addressing polypharmacy and subsequent medication-related problems in older adults.

Medication-Related Problems

Medication-related problems are defined as undesirable medication-related events experienced by patients[33] that may interfere with patient outcomes. These may include instances of intentional or unintentional medication underuse or overuse (eg, duplicative prescribing within the same drug class), use of potentially inappropriate or high-risk medications, drug interactions, and adverse drug events.

An adverse drug event includes preventable and nonpreventable events occurring from medication use and misuse and accounts for errors related to prescribing and administration.

Adverse events are common during transitions between care settings, and up to 31% of hospitalizations of older persons involve adverse drug events.[34] The use of potentially inappropriate, high-risk medications such as anticholinergics, antipsychotics, opiate analgesics, and hypnotics, along with polypharmacy, increases the risk of adverse drug events.[32],[35] Adverse drug events may be underreported and be difficult to detect in older patients because they often present atypically and with nonspecific symptoms, such as lethargy, confusion, lightheadedness, or falls. Such unrecognized adverse drug events may be treated with additional drugs, causing a

prescribing cascade that further increases polypharmacy and its risks. Nevertheless, most adverse reactions represent extensions of a drug's pharmacologic effect, have identifiable predictors, and are potentially preventable.[36] Nearly 1 in 25 community-dwelling older adults is potentially at risk for a major drug–drug interaction.[37] Careful medication regimen review (MRR) is essential to identify and systematically address potential medication-related problems in older adults.[38]

CASE 107-2

Question 1: T.M. is a 73-year-old female who comes to a "brown bag" session at the local senior center. She reports recently feeling "sluggish" and dizzy. She lives at home alone on a modest, fixed retirement income. T.M.'s chronic medical problems include coronary artery disease (CAD), HF, HTN, diabetes, and hyperlipidemia. She states that different specialists prescribe her "a lot of medications," but she does not know their names. She reports that she skips her medications periodically when she does not feel well. T.M. usually maintains an active social life; however, because of the recent weakness, she has not gone out as much. She is interested in natural medicines and self-medicates with nonprescription medications and herbal remedies. Review of her brown bag reveals the following: glipizide 2.5 mg twice daily, hydrochlorothiazide 25 mg daily, atenolol 50 mg daily, digoxin 0.25 mg daily, nitroglycerin (NTG) 0.4 mg sublingual (SL) as needed, ramipril 5 mg twice daily, furosemide 40 mg twice daily, metformin 500 mg twice daily, niacin ER 500 mg once daily, acetylsalicylic acid (ASA) 81 mg daily, acetaminophen 500 mg as needed, multivitamins with minerals, calcium carbonate 500 mg three times a day, coenzyme Q-10 90 mg daily, and ibuprofen 200 mg as needed. She also drinks a glass of red wine with dinner.

What initial steps are necessary for safe and effective management of T.M.'s drug therapy?

Like many ambulatory older patients who are being treated for multiple chronic medical conditions, T.M. is at high risk for medication-related problems secondary to nonadherence, medication errors, prescribing from multiple providers, self-medicating, and polypharmacy. She is representative of more than nine million older adults who live at home alone. The isolated community-dwelling older patient is typically female, age 75 years or

older, has multiple medical issues, and takes multiple medications.[1] With rising life expectancy, the increased complexity of managing multiple medical conditions has put nonhospitalized elderly individuals at higher risk of experiencing adverse drug reactions and for adverse drug-related admissions.[36] Another group of older individuals at higher risk of having adverse drug reactions are those who are recently discharged from the hospital. The postdischarge period is often a time of confusion, and older patients may have difficulty coping and sorting out new versus replacement or duplicate drugs. A summary of the various factors contributing to nonadherence in the older patient is presented in **Table 107-6**.[39]

Table 107-6
Factors Influencing the Inability to Adhere to a Medication Regimen

Low health literacy (understanding of medication instructions and importance)
Medication cost
Significant cognitive or physical impairment (eg, memory, hearing, vision)
Inconsistent filling or refilling of prescriptions
Adverse effects
Lack of clinical evidence of effectiveness

Source: Adapted from Bosworth HB, Granger BB, Mendys, et al. Medication adherence: a call for action. *Am Heart J*. 2011;162(3):412–424. © 2011 Elsevier. With permission.

T.M. needs a primary care provider to coordinate her medical care and to evaluate the new-onset sluggishness and dizziness. She should also be advised to establish a client–patient relationship at a specific pharmacy for all her medications to be on one profile for continuous assessment. Furthermore, T.M. should be counseled to discontinue alcohol, which can interact with several of her current medications and worsen her conditions. Finally, a comprehensive medication review with a pharmacist to identify and resolve existing and potential medication-related problems is highly recommended.

APPROACH TO APPROPRIATE PRESCRIBING AND DEPRESCRIBING

As a result of high rates of multimorbidity and polypharmacy, initiatives such as the American Board of Internal Medicines' Choosing Wisely Campaign have focused on the proactive avoidance of unnecessary tests, procedures, and medications, particularly among older adults.[40] Effective implementation of these initiatives is likely to require the input of interprofessional team members, including pharmacists. Deprescribing, the process of identifying and discontinuing medications where risks of continuing drug therapies may outweigh the benefits, has also been the focus of multiple initiatives. Effective deprescribing relies on a thorough understanding of patient characteristics as well as medication pharmacology and pharmacokinetics. As such, pharmacists have a critical role in both the conduct of a medication review and the deprescribing process.

DISEASE-SPECIFIC GERIATRIC DRUG THERAPY

Cardiovascular Disease in the Ambulatory Older Patient

Case 107-2, Question 2: T.M. presents to the multidisciplinary geriatric care team on the advice of pharmacists at the brown bag session. During the intake interview, she admits to selective adherence to medications based on how they make her feel and their costs. She reports that she has not taken her furosemide because she feels that it is contributing to her sluggishness and dizziness. Her wine intake with dinner is 8 to 12 ounces most days of the week. T.M.'s medical history and physical examination are as follows: 73-year-old White female, 66 inches (167.64 cm), 189 pounds (85.72 kg); vital signs are as follows: blood pressure (BP), 158/82 mm Hg; heart rate (HR), 54 beats/minute; temperature, 98.7 °F (37.05 °C); and respiratory rate, 18 breaths/minute. Pertinent laboratory values are as follows:

SCr, 1.3 mg/dL
Blood urea nitrogen, 35 mg/dL
Sodium, 153 mEq/L

Potassium, 3.4 mEq/L
Magnesium, 1.5 mEq/L
Glucose, 250 mg/dL
Glycated hemoglobin ($HgbA_{1c}$), 8.5%
Total cholesterol, 259 mg/dL
Low-density lipoprotein, 120 mg/dL
High-density lipoprotein, 40 mg/dL
Triglycerides, 200 mg/dL
Urine dipstick, 2+ protein
Digoxin level, 1.5 ng/mL

Electrocardiogram showed sinus bradycardia with an old anterior myocardial infarction (MI). Echocardiogram showed an ejection fraction (EF) of 35%. Her problem list includes new-onset sluggishness and fainting, chest pain and shortness of breath (SOB) on exertion, 3(+) pitting edema bilaterally, New York Heart Association (NYHA) classes II–III HF, HTN, type 2 diabetes, obesity, excessive alcohol intake, CAD, and hyperlipidemia. What factors may be contributing to T.M.'s feeling of sluggishness and dizziness?

T.M.'s sluggishness and dizziness are most likely caused by her low HR, somewhat dehydrated state, and multiple medications that have the potential for producing these symptoms.

Specifically, digoxin 0.25 mg daily is considered a high dose; 0.125 mg daily should be used as initial therapy in patients older than 70 years to limit the development of toxicities resulting from age-related decline in renal function. T.M.'s CrCl is reduced, nearing 45 mL/minute; this, combined with her low potassium level, may increase her risk of digoxin toxicity. Further, her digoxin level is elevated at 1.5 ng/mL (therapeutic range 0.5–0.9 ng/mL). Therefore, the digoxin dose should be lowered to 0.125 mg daily.[41] If HF symptoms remain stable on the reduced dose, a discontinuation trial may be warranted.

T.M.'s β-blocker may also contribute to her symptoms, particularly as atenolol is renally cleared. The β-blockers, such as carvedilol, metoprolol, and bisoprolol, have been proven to reduce morbidity and mortality in patients with HF and are clinically indicated.[42],[43] As such, T.M. should be switched to an equivalent dose β-blocker indicated for HF, such as extended-release metoprolol, which may further reduce T.M.'s medication burden. If fatigue and bradycardia

persist despite these changes and are not tolerable, the β-blocker therapy could be de-intensified after careful weighing of risks (eg, symptomatic bradycardia) and benefits (eg, mortality reduction) as well as patient-specific goals of care.

HEART FAILURE

Case 107-2, Question 3: What is appropriate management for T.M.'s stage of HF?

On the basis of T.M.'s history of an old MI evidencing structural heart disease, her low EF, and the presence of fluid-retention symptoms, T.M. is in stage C HF based upon the American College of Cardiology/American Heart Association classification scheme (see Chapter 14, Heart Failure). HF is a common cause of morbidity and mortality in older patients. The standard therapy for HF with reduced EF typically consists of ACE inhibitors or angiotensin-receptor blockers (ARBs) of target doses and specific β-blockers indicated for HF. In symptomatic patients, diuretics may be used for symptomatic relief, and an aldosterone antagonist for its morbidity and mortality benefits. In patients who remain symptomatic despite optimal therapy, guidelines recommend the use of sacubitril/valsartan in place of ACE inhibitors or ARBs to further reduce the risk of death and/or hospitalization.[42,43] Concurrent behavior modification with weight loss and salt restriction will also allow better control of HF.

Case 107-2, Question 4: In addition to the digoxin de-intensification and β-blocker adjustments mentioned earlier, what changes can be made to optimize T.M.'s therapeutic regimen for HF?

It was noted during T.M.'s brown bag medication review that she was taking both a loop and a thiazide diuretic—a therapeutic duplication. Such duplications may often be unintentional, occurring as a result of systematic failure to reconcile medications with patients, particularly during transitions of care. As loop diuretics are

generally more effective than thiazide diuretics in providing symptomatic relief, particularly in moderate-to-severe renal compromise, the thiazide should be discontinued.[44] Discontinuing the hydrochlorothiazide (HCTZ) will likely help with T.M.'s hypokalemia and slightly dehydrated state. Regular monitoring of SCr, urea nitrogen, sodium, and potassium is essential while on diuretics. Older adults may be particularly bothered by increased urination while taking diuretics. If this is a concern for T.M., she may be advised to take furosemide separate from social engagements. It may also be valuable to change T.M.'s twice-daily ramipril to a once-daily ACE inhibitor to reduce medication burden, particularly if T.M. is having difficulty managing her medications. Further, an aldosterone antagonist should be considered for T.M. to reduce the risk of hospitalizations in HF and to provide added BP control for T.M. If BP control can be achieved, transition from an ACE inhibitor to sacubitril/ valsartan would provide additional benefits mentioned earlier.

CARDIOVASCULAR DISEASE AND HYPERLIPIDEMIA

Case 107-2, Question 5: T.M. reports that she does not take her niacin ER 500 mg because she experiences facial flushing. Despite her history of MI, she does not believe that cholesterol and "heart disease" are major health concerns for a female who has lived to her age. What information can you provide her about cholesterol and the risk of cardiovascular disease (CVD) in patients like her?

Approximately two-thirds of CVD deaths occur in people age 75 years and older. For those age 60 to 79 years, the prevalence of CVD is ~70%; this rises to ~85% in those age 80 years and older. Although male sex is an independent risk factor for CVD, more females than males die from heart attacks because these events occur in females at an older age. The significantly higher rate of hypercholesterolemia in females seems also to predict a higher CVD risk than for males later in life. Therefore, it is important to treat dyslipidemia with a statin in most patients with clinical atherosclerotic

cardiovascular disease (ASCVD), in those age 40 to 75 years with diabetes who have low-density lipoprotein cholesterol (LDL-C) levels of 70 to 189 mg/dL, and in those without diabetes and an estimated 10-year ASCVD risk ≥7.5%.[45] In those older than 75 years, a clinical assessment and discussion of risks and benefits of therapy is warranted. Often, this entails continuation of statins in patients who are already taking and tolerating therapy unless functional decline, multimorbidity, frailty, or reduced life expectancy might limit benefits.

CASE 107-2, QUESTION 6: What is an optimal therapeutic plan for the management of T.M.'s hyperlipidemia?

T.M. is a 73-year-old female with a history of diabetes, with elevated cholesterol and BP conferring a 10-year ASCVD risk >7.5%. T.M.'s treatment plan should begin with lifestyle and dietary modifications. Based on her high ASCVD risk level and concomitant diabetes, a high-intensity statin should be started to lower LDL by at least 50%. However, the relative benefits of statin therapy should be weighed against the potential risk of adverse reactions, including dyspepsia, liver dysfunction, and muscle-related effects. Although rare, older adults, particularly the frail elderly with low body mass, may be at increased risk for muscle-related side effects. The hydrophilic statins, those with limited cytochrome P-450 metabolism, and those less effected by renal impairment may cause fewer side effects and drug interactions. These agents and those with long half-lives may also simplify administration for patients such as T.M. Finally, because alcohol can increase triglycerides, abstinence is strongly recommended.[46]

Clinical guidance for the care of adults older than 75 years with hyperlipidemia is limited by the lack of clinical trial data. Current guidelines[45] recommend for the continuation of currently tolerated statins as patients age, particularly for secondary prevention, as evidence generally supports their use through age 85.[47] If new statin initiation is required after age 74 years, a careful assessment of risk versus benefit is warranted, and guidelines recommend for

consideration of moderate- to high-intensity statins in secondary prevention. The evidence supporting the use of statins for primary prevention in this age group largely depends on patient-specific factors, including medical conditions, such as the presence of high cardiovascular risk or vascular dementia, functional status, and overall prognosis.

Case 107-2, Question 7: What other interventions should be implemented to optimize the management of T.M.'s CAD?

Any strategy to optimize the management of T.M.'s CAD should take into consideration the patient's functional status, comorbidities, and risks versus benefits. β-Blockers and ACE inhibitors are indicated in patients who have CAD and HF to prevent further ventricular remodeling. As such, the aforementioned changes to T.M.'s β-blocker and ACE inhibitor should be implemented.

In addition, statins should be utilized in CAD to prevent further endothelial injury from atherosclerosis and plaque rupture.

HYPERTENSION

Case 107-2, Question 8: T.M. has uncontrolled HTN. How should this be managed in light of her advanced age?

Despite her advancing age, T.M.'s BP is well above the goal of <130/80 as recommended for noninstitutionalized, ambulatory, community-dwelling older adults by the 2017 American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines for High Blood Pressure in adults.[48] HTN is present in more than two-thirds of individuals older than 65 years. Despite having the highest prevalence of HTN, only half of those age 60 years and older are adequately controlled.[49] Uncontrolled BP[48] in this population contributes to morbidity, mortality, as well as premature disability and institutionalization. Numerous clinical trials have demonstrated significant benefits to BP lowering in ambulatory

older adults like T.M. Serious side effects of aggressive BP lowering include orthostatic hypotension, bradycardia, acute kidney injury, and hypokalemia; these effects must be diligently monitored during titrations. In older adults with a high burden of comorbidity or limited life expectancy, a patient-centered approach to goal setting is warranted.

For T.M., it is recommended that adequate doses of furosemide and an ACE inhibitor or ARB with close monitoring be the main therapeutic approach for her HTN. Extended- or controlled-release formulations of metoprolol or carvedilol should be considered for HF management. As it appears additional BP control will likely be warranted, the use of an aldosterone antagonist should be considered in light of her HF stage. If an aldosterone antagonist is added, careful monitoring of renal function and potassium will be necessary to avoid an adverse drug event with her remaining medications.

Diabetes in the Older Adult

Case 107-2, Question 9: T.M. reports that she frequently feels lightheaded and shaky after she takes the glipizide and wonders if her A_{1C} is too low. What is an optimal therapeutic plan for the management of T.M.'s diabetes?

Healthy older adults with few coexisting chronic illnesses and intact cognitive function and functional status should have an A_{1C} target of 7% to 7.5%, whereas those with multiple coexisting chronic illnesses, mild-moderate cognitive impairment, or impairment in two or more IADLs should aim for an A_{1C} goal of 7.5% to 8%. Those with very complex or poor health, such as those with long-term or end-stage chronic illness, moderate-severe cognitive impairment, or impairment in two or more ADLs should have an A_{1C} goal of 8% to 8.5%.[50,51] In light of T.M.'s intact cognitive and functional status, as well as limited coexisting chronic illnesses, her A_{1C} target should be 7% to 7.5%.

Management of T.M.'s diabetes should include comprehensive diabetes education, focusing on the importance of weight loss, self-monitoring of blood glucose, alcohol abstinence, and medication adherence. T.M.'s alcohol consumption and self-reported erratic meal schedule may be contributing to the hypoglycemia as well as to the worsening of her HTN and HF. Glipizide is a second-generation sulfonylurea that carries a lower risk of hypoglycemia than first generation, more renal-dependent sulfonylureas. However, older adults are more susceptible to hypoglycemia even at low doses and may have difficulty recognizing the symptoms. As such, the glipizide should be discontinued.

Metformin is the preferred, initial pharmacologic agent for the management of diabetes.[51] Considering T.M.'s renal decline, her metformin should be continued at the reduced dose of 500 mg twice daily. If adequate glycemic control is not maintained on metformin alone, patients should be assessed for clinical ASCVD, HF, chronic kidney disease (CKD), and/or indicators of high ASCVD risk. If present, therapy such as glucagon-like peptide 1 receptor agonists (GLP1-Ras) or sodium glucose cotransport 2 inhibitors (SGLT2i) with proven ASCVD, HF, or CKD benefits should be utilized. For both of these classes of agents, the propensity for hypoglycemia is low and may be favorable in high-risk older adults like T.M. The use of SGLT2i in older adults may be limited by their renal dosing limitations, increase in urinary volume, and potential for hypovolemia and hypotension. T.M.'s current kidney function precludes the use of an SGLT2i. T.M. may benefit, however, from the use of a GLP1-Ra with proven CVD benefit, such as liraglutide, dulaglutide, or semaglutide. As liraglutide may additionally confer a reduction in progression of CKD, this would be an ideal agent to select for T.M. The dosage should be titrated, and T.M. should be monitored for adverse GI events, such as nausea, diarrhea, and reduced appetite.

Depression and the Older Patient

Depression is one of the most prevalent mental disorders in older adults and occurs in ~7% to 15% of those age 60 years and older.[52,53] Depression is often overlooked and may be underreported because many people are not comfortable discussing depression, even though it is a major risk factor for suicide. Older patients may be at increased risk for depression because of the high prevalence of comorbid medical conditions (eg, stroke, cancer, MI, rheumatoid arthritis, dementia, Parkinson disease, diabetes mellitus [DM]).[54] They also may experience depression because of the death of a spouse, social isolation, loss of independence, functional, or cognitive decline.[55] (See Chapter 86, Depressive Disorders for further discussion of risk factors for depression and potential drug-induced causes.)

CASE 107-3

Question 1: J.W. is a 79-year-old female who is married, 68 inches (172.72 cm), 110 pounds (49.89 kg). She presents for a psychiatric evaluation. Her husband says she just has not been herself lately. The changes in J.W. began on a family vacation 6 months earlier when she got lost on the cruise ship. Since that incident, she has become increasingly anxious and has developed insomnia. Although she does not feel sad or "depressed," she generally does not feel well. J.W.'s normally positive attitude toward life has become pessimistic. Her husband confirms that she has become more forgetful and no longer enjoys eating. In fact, she has lost 18 pounds (8.16 kg) during the past 2 months. J.W. no longer does her volunteer work at the local children's center. She says she wants to die because she is no longer the person she used to be, but she denies having any specific suicidal thoughts. Her medical history is significant for diabetes and HTN, which are both well controlled on glipizide 5 mg every morning and hydrochlorothiazide 25 mg daily. Her medical evaluation and physical examination are unremarkable. Laboratory results and head computed tomography scan are within normal limits. J.W. is diagnosed as having a major depressive episode.

What symptoms of depression are present in J.W.?

J.W.'s presenting symptoms are typical of major depression in an older patient, which is commonly quite different from that of younger patients with depression. Criteria set forth in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, for diagnosing

depression were developed using younger subjects and may not be applicable to the older patient with depression.[54] Older patients are less likely to report suicidal thoughts but are more likely to experience weight loss as a symptom of depression. Anxiety, irritability, somatic problems, or a withdrawal from normal activities, as exhibited by J.W., may be more significant features in late life depression than depressed mood. Memory problems, such as J.W.'s forgetfulness, may be attributable to a lack of concentration or effort stemming from her depression. This is distinct from dementia, which manifests itself predominantly with impairment in short- and long-term memory (see Chapter 108, Geriatric Neurocognitive Disorders). Therefore, depressed mood cannot be relied on for determining whether an older patient has a depressive disorder.[55] **Table 107-7** lists atypical depressive symptoms that may be found in older adults. The presence of any one of these symptoms should be considered a red flag and should prompt further evaluation for major depression.

Table 107-7
Atypical Depressive Symptoms in Older Adults

Cognitive changes
Fatigue
Pain
Refusal to eat or drink
Refusal to take medication
Self-care changes
Social withdrawal
Weight loss

Source: Kok RM, Reynolds CF. Management of depression in older adults: a review. *JAMA*. 2017;317(20):2114–2122. doi:10.1001/jama.2017.5706.

CASE 107-3, QUESTION 2: J.W.'s physician decides to prescribe an antidepressant. Which antidepressants are preferred for use in older adults?

Selection of an antidepressant drug for an older adult must take into consideration age-related changes in pharmacokinetic, pharmacodynamic, and physiologic parameters that make this population more vulnerable to adverse effects. Although the available antidepressants are equally effective, selective serotonin reuptake inhibitors (SSRIs) are better tolerated than older agents, such as the tricyclic antidepressants. Therefore, low-dose SSRIs should be considered a first-line therapy for older patients. Previous recommendations were to start citalopram; however, doses of citalopram over 20 mg daily are not recommended because of the risk of QTc prolongation in adults older than 60 years.[56] Of course, this does not preclude the use of sound clinical judgment that incorporates the patient's history of response, comorbidities, and the drug's side-effect profile. J.W. should start taking an SSRI, such as escitalopram 10 mg daily.[57] Alternatives include sertraline or duloxetine, a serotonin–norepinephrine reuptake inhibitor (SNRI). If J.W. has minimal or no response to escitalopram, her therapy should be switched to duloxetine, venlafaxine, or desvenlafaxine as alternatives. It may take 8 to 12 weeks before assessment of J.W.'s full response can be made.[58] There is limited evidence on how long an older adult should continue therapy; however, continuing treatment for 1 year may decrease the risk of depressive symptoms returning.[53] J.W. should be assessed periodically for efficacy of treatment and adverse effects.

Asthma and Chronic Obstructive Pulmonary Disease in the Older Adult

The prevalence of asthma in adults age 65 years and older is estimated to be 7.8%, and 62.9% of these patients are considered uncontrolled.[59],[60] Older adult rates of asthma-related hospitalization and mortality are high, possibly because of underdiagnosis and undertreatment of the disease.[61] Symptoms of asthma, including wheezing, cough, chest tightness, and dyspnea, are similar in both older and younger patients (see Chapter 18, Asthma). However,

because the older adult is more likely to have coexisting medical conditions (eg, HF, angina, chronic obstructive pulmonary disease [COPD], gastroesophageal reflux disease [GERD]) with symptoms that mimic asthma, accurate diagnosis and assessment of severity is often difficult.[62]

COPD is largely a disease of older patients with a prevalence of as high as 11.2% in those age 75 years and older.[63] It is the fourth leading cause of death in the world.[64] This chronic condition is a major cause of morbidity and mortality in the older population and is often undiagnosed as it may be mistaken as a "normal" part of the aging process and may be confounded by physical deconditioning or comorbidities such as HF.[65] Drug therapy for COPD in the older adult does not differ significantly from standard management regimens (see Chapter 19, Chronic Obstructive Pulmonary Disease). Factors associated with aging such as changes in vision, hearing, and comorbid conditions are associated with poor adherence to medication regimens. Older adults may also be more sensitive to adverse effects of pharmacologic agents.

CASE 107-4

Question 1: J.C., a 67-year-old female, 66 inches (167.64 cm), 145 pounds (65.77 kg), presents to the ED with SOB for the past 2 days. She was in her usual state of health until 4 days ago when she exhibited flu-like symptoms consisting of fever, cough, and mild wheezing. J.C. has a history of asthma, diabetes, HTN, headache, and GERD. Her current medications include glipizide 5 mg daily, lisinopril 10 mg daily, metoprolol 50 mg twice daily, lansoprazole 30 mg daily, ibuprofen 200 mg every 6 hours as needed for headache, albuterol metered-dose inhaler (MDI) 2 inhalations four times a day as needed for SOB, and fluticasone DPI (100 µg) 1 inhalation twice daily. Her drug regimen has been unchanged for the past 2 years, and she reports taking all medications as prescribed. The only recent change has been the need for albuterol every 3 to 4 hours for coughing and wheezing during the past few days.

What factors (including medications) may have contributed to her acute asthma exacerbation?

Management of acute asthma exacerbations in previously stable older adults with asthma should begin with a review of the

medication history for asthma-inducing agents. Aspirin and other NSAIDs are known to induce acute bronchoconstriction in adults with asthma.[66] J.C. should be queried about her previous (especially recent) use of ibuprofen in relation to her asthma symptoms, and these agents should be avoided if associated. An alternative agent for pain control is acetaminophen. Nonselective β-blockers, including topical ophthalmic formulations, can precipitate acute bronchoconstriction and should be avoided in patients with reactive airway disease.[67] Although cardioselective β-blockers are generally considered safe for use in patients with asthma, it is important to recognize that cardioselectivity may be lost with higher dosages. Because J.C. has been taking low-dose metoprolol (a cardioselective agent) for years without problem, this medication is unlikely to be contributing to her current asthma exacerbation. One of the most important triggers for asthma exacerbations is respiratory infection, particularly viral. J.C. reports the recent onset of symptoms consistent with influenza, and this is likely precipitating her current pulmonary symptoms. As a future prophylactic measure, J.C. should be counseled to receive the influenza vaccine annually. J.C. does not recall ever receiving the pneumococcal vaccine. In adults age 65 years and older who are not immunocompromised, and who have never received the pneumococcal vaccine, or who are unsure like J.C., they should receive one dose of the pneumococcal polysaccharide vaccine (PPSV23).[68] (See Chapter 64, Vaccinations.)

Case 107-4, Question 2: Are the medication regimens used to treat asthma in older adults different from those used in children and younger adults? Should J.C.'s maintenance of asthma regimen be changed?

Medications used in the management of persistent asthma in older adults are similar to those used in younger patients and consist of bronchodilators in combination with anti-inflammatory agents (see Chapter 18, Asthma). Drug selection and monitoring may be more complicated because of the greater likelihood of coexisting medical

conditions and increased potential for drug–disease and drug–drug interactions.

Inhaled β_2-agonists are an important class of drugs used to treat asthma in all age groups. The low incidence of drug interactions and reduced side-effect profile make inhaled β_2-agonists ideal for use in the older adults with asthma. However, these agents can cause dose-dependent systemic side effects, such as tremor, tachycardia, hypokalemia, and arrhythmias, which are of particular concern in patients with cardiac conditions.[67] Inhaled corticosteroids are the preferred treatment for all forms of persistent asthma, yet they may be underused in the older adult. Though generally well tolerated, older adult patients receiving high-dose therapy are at an increased risk for osteoporosis, cataracts, skin thinning, and bruising.[69] In addition to the well-known complications associated with systemic corticosteroid use (see Chapter 44, Rheumatoid Arthritis), these agents can acutely cause confusion, agitation, and hyperglycemia.

J.C. is currently maintained on low doses of an inhaled corticosteroid (fluticasone) in combination with a short-acting β_2-agonist (albuterol), and this is an appropriate regimen for a patient with mild persistent asthma. Following resolution of her viral infection, J.C.'s asthma control should be reevaluated within the next 3 months for a step-up or step-down in therapy. Because J.C. is postmenopausal, she is at risk for osteoporosis; calcium and vitamin D supplementation should be initiated (see Chapter 110, Osteoporosis).

Appropriate use of inhalers is difficult for most patients but may be particularly problematic in the older adults because of decreased hand strength or arthritis, difficulty actuation timing to inhalation, or impaired mental function. The use of spacer or holding chamber devices may minimize the coordination necessary for proper use of an MDI and may reduce the incidence of systemic and local (cough, hoarseness, thrush) side effects associated with inhaled corticosteroids. J.C. is using a DPI, and even though J.C. previously used a DPI, she should be asked to demonstrate her technique and reinstructed, if necessary, to ensure she is using the inhaler correctly.

If J.C. is unable to use her inhaler appropriately, use of nebulized solutions may be considered.

Infectious Diseases in the Older Adult

Infections are among the most common problems in older adults and are a significant cause of morbidity and mortality.[70] Infections are also one of the most frequent reasons for hospitalization of older ambulatory persons. Antibiotic therapy for an infection in older adults may be delayed because they may present with atypical or nonspecific signs and symptoms. The older population is also more likely to have polymicrobial infections than younger people, and changes in renal function should be taken into account when selecting, dosing, and monitoring antibiotic therapy.

PNEUMONIA

Case 107-4, Question 3: J.C. was admitted to the hospital and given IV methylprednisolone for 4 days. She was then discharged home with a new prescription for prednisone 40 mg daily for 7 days. Three days after J.C. was discharged from the hospital, she presented again to the ED. She was accompanied by a neighbor who noted that J.C. suddenly became forgetful and confused and continues to have difficulty breathing. Her neighbor reports that J.C. has been staying in bed for the past 2 days and has not eaten much. J.C. has a low-grade fever, and chest examination reveals faint breath sounds with light crackling rales over her right lung base. A chest radiograph confirms the diagnosis of pneumonia. How is J.C.'s clinical presentation consistent with community-acquired pneumonia (CAP) in the older adult?

CAP is the most prevalent cause of sepsis worldwide[71] and one of the leading causes of hospitalization and death due to infection in adults in the United States.[72] In a large population-based study of CAP, adults age 65 to 79 years were found to have an incidence of pneumonia requiring hospitalization that was nine times as high as those age 18 to 49 years and 25 times as high in those age 85 years and older.

Risk factors for CAP in all adults include age greater than 65 years, COPD, smoking, alcoholism, aspiration, and chronic medical conditions such as heart, renal, and liver disease.[73],[74] *Streptococcus pneumoniae* is the most common cause of CAP in the older adult.[71]

Respiratory symptoms and fever are often subtle or absent in older patients with pneumonia, and instead, like J.C., they may present only with altered mental status (delirium, acute confusion, memory problems) or a decline in functional status. Delirium or acute confusion is a common presentation in older patients who may have new-onset lower respiratory infection.

CASE 107-4, QUESTION 4: How should J.C. be treated for her respiratory infection?

In many cases, management of pneumonia in the older adult requires hospitalization because they are at higher risk for mortality and complications. Early empiric antibacterial therapy is particularly important for older patients with pneumonia (see Chapter 67, Respiratory Tract Infections). J.C. should be hospitalized again and treated aggressively for pneumonia with broad-spectrum IV antibiotics. The Infectious Diseases Society of America/American Thoracic Society Consensus Guidelines on the Management of Community-Acquired Pneumonia in Adults recommends treatment of most hospitalized nonintensive care unit (ICU) patients with a combination of B-lactam (ampicillin + sulbactam, cefotaxime, ceftriaxone, or ceftaroline) and a macrolide (azithromycin or clarithromycin) or a respiratory fluoroquinolone (levofloxacin or moxifloxacin).[75]

PREVENTION

CASE 107-4, QUESTION 5: After 3 days of hospitalization, J.C. is clinically stable and discharged home with an oral antibiotic. J.C. should be treated for a minimum of 5 days and be afebrile for 48 to 72 hours before the antibiotic is discontinued. What preventative measures are available to J.C. after being discharged?

Once patients are stable and ready to be discharged home, they should be switched to oral antibiotics to complete their therapy at home.

Both influenza and pneumococcal vaccinations are beneficial and recommended in the prevention of CAP.[76,77]

The Centers for Disease Control and Prevention (CDC) recommends pneumococcal conjugate vaccine (PCV13) in patients age 65 years and older with immunocompromised conditions, cerebrospinal fluid (CSF) leaks, or cochlear implants. For patients who are not immunocompromised such as J.C., one dose of PPSV23 is recommended at age 65 years and older at least 5 years after their first dose (see Chapter 64, Vaccinations).

J.C.'s immunization status should be confirmed, and as a preventative measure, J.C. should be offered both influenza and pneumococcal vaccines upon discharge.

URINARY TRACT INFECTION

CASE 107-5

Question 1: A.H. is a 72-year-old Hispanic female who is currently wheelchair-bound because of pain in her right hip. Her granddaughter brings A.H. to the geriatric clinic because she has recently developed urinary incontinence. She has a documented allergy to "sulfa." Her granddaughter reports that A.H. has been feeling weak for the past 2 days and fell while getting out of the wheelchair. A urinalysis indicates the presence of a urinary tract infection (UTI).

Are A.H.'s symptoms typical of UTIs?

UTIs are common in older patients and represent 25% of all infections in this population.[78] Clinical symptoms often vary from patient to patient making diagnosing UTIs more difficult and may include dysuria, hematuria, urinary frequency, urinary incontinence, pyuria, and fever.[79,80] Some older patients may present with delirium or sudden changes in mental status, confusion, or falls.[81] Bacteriuria is often asymptomatic in older adults, or patients may have nonspecific symptoms. The prevalence of asymptomatic bacteriuria

for those age 70 years and older ranges from 3.6% to 50%, being the highest in long-term care, and may not always require antibiotic treatment.[81] Impaired voiding with residual urine in older females and obstructive uropathy from prostatic disease in older males predispose them to bacteriuria.[82] The severity of UTIs in the older population ranges from mild cystitis to life-threatening urosepsis, and both are more difficult to treat because of resistant organisms and age-related decreases in host defenses.

A.H.'s presentation of weakness, urinary incontinence, and a recent fall is a consistent pattern of nonspecific symptoms, and a urinalysis confirmed a UTI. Major pathogens in those older than 65 years with uncomplicated cystitis are include *Escherichia coli*, *Klebsiella oxytoca*, and *Proteus mirabilis*[78] (see Chapter 71, Urinary Tract Infections).

Case 107-5, Question 2: A.H. is prescribed a 7-day course of ciprofloxacin 250 mg po twice daily. Is this drug therapy appropriate?

Oral antibiotics, such as nitrofurantoin and sulfamethoxazole–trimethoprim, are appropriate for most patients with symptomatic UTI, reserving fluoroquinolones as alternatives when patients cannot tolerate or are allergic to the standard treatment.[83] An important consideration of antibiotic therapy for older adults with UTI is impaired renal function. Nitrofurantoin should not be used in those patients with CrCl <30 mL/minute due to the potential of peripheral neuropathy, hepatic toxicity, and pulmonary toxicity.[24]

Ciprofloxacin is a reasonable choice for A.H. because she is allergic to sulfa and *E. coli* is the most likely causative agent. Fluoroquinolones carry a black box warning because of the risk of serious adverse reactions that include tendinitis, tendon rupture, peripheral neuropathy, and CNS effects (seizures, increased intracranial pressure, dizziness, and tremors).[84] Along with renal function, monitoring should include symptoms of tendon inflammation or pain and changes in mental status.[85]

Osteoarthritis

Osteoarthritis affects about 302 million people worldwide and ~54.4 million people in the United States.[86],[87] Osteoarthritis may lead to decreased mobility, falls, and loss of independence in older adults.[87] Nonpharmacologic management of osteoarthritis, such as physical and occupational therapy, weight loss in patients who are overweight and obese, and exercise, is recommended to decrease pain and improve function, either alone or in combination with appropriate analgesics.[86]

CASE 107-6

Question 1: C.W., a 71-year-old retired schoolteacher, has been suffering from mild osteoarthritis of his hands for 5 years. He is an active older adult who enjoys volunteer work at the local hospital. He presents to the geriatric clinic with increased heartburn and gastric reflux symptoms. His past medical history is significant for diabetes, HTN, hypercholesterolemia, and GERD. C.W.'s current medications include glipizide 10 mg daily, verapamil sustained-released 240 mg daily, atorvastatin 10 mg daily, famotidine 20 mg twice daily, docusate sodium 100 mg twice daily, and ibuprofen 200 mg four times a day as needed.

What modifications can be made to his drug regimen to control his arthritis pain and minimize side effects from his pain medication?

Acetaminophen and/or over-the-counter (OTC) NSAIDs are the first-line therapies for mild-to-moderate arthritis pain.[86] Though pain control with acetaminophen may be inferior to NSAIDs, its reduced GI and renal toxicity provides an advantage in older patients who may be more susceptible to the adverse effects of NSAIDs. Doses of acetaminophen should not exceed 3 g a day in older adults,[86] and, in those with a history of alcohol misuse or hepatic impairment, the American Geriatric Society recommends reducing the maximum daily dose by 50% to 75%.[88] If C.W. has not tried acetaminophen in the past for his arthritis pain, acetaminophen 325 to 500 mg every 4 hours or 500 to 1000 mg every 6 hours, not to exceed 3 g a day, may be initiated. Older patients with osteoarthritis pain often find relief from NSAIDs, which should be used with caution because of their potential GI complications, renal toxicity, and cardiovascular

risks. Topical NSAIDs are recommended before starting oral NSAIDs.[86] Advanced age is a major risk factor for NSAID-associated renal toxicity, such as sodium and water retention, as well as risk for HTN.[89] Thus, ibuprofen may be contributing to C.W.'s increased GERD symptoms and to his HTN.

Case 107-6, Question 2: C.W. reveals that he has tried acetaminophen without much relief of his pain. What other pain medication options does C.W. have?

If acetaminophen is not effective, the 2019 American College of Rheumatology/Arthritis Foundation Guidelines for Osteoarthritis of the Hand recommend a topical NSAID as the next step of treatment.[86] C.W. could be started on diclofenac 1% gel to be applied topically. For osteoarthritis of the hands, the usual adult dose is 2 g (2.25 inches) four times a day.[90] The maximum dose is 32 g daily over all joints and 8 g to any single joint.

For patients with moderate-to-severe chronic pain caused by osteoarthritis, a low-dose opiate may provide relief from pain with minimal adverse drug effects (see Chapter 55, Pain and Its Management). Of particular concern in older adults are the risks of falls, delirium, and constipation with opioid medication use. Codeine and tramadol are "weak" opioids that have ceiling effects, generally do not provide adequate analgesia, and may carry dangerous side effects in the older adult. Meperidine should also be avoided in older adults because of its high potential for CNS side effects, especially in those with reduced renal function.

LONG-TERM CARE FACILITIES

The LTCF environment is governed in part by the Omnibus Budget Reconciliation Act (OBRA), as well as by numerous other laws and regulations, which are contained in the federal Centers for Medicare and Medicaid Services (CMS) publication, States Operations Manual

(SOM).[91] The federal mandates include a monthly MRR by a pharmacist of each resident's medical record to help ensure each resident's regimen is free from unnecessary drugs and that their medication regimen helps to support their mental, physical, and psychosocial well-being. Medication regimens are reviewed to determine the following:

1. Is each medication clearly indicated?
2. Have therapeutic goals been established for chronic drug therapies?
3. If indicated, is each medication being dosed and administered appropriately?
4. Are any real or potential problems with medication side effects or interactions present?
5. If psychotropics are being prescribed, have nonpharmacologic approaches been used first? Has their use been justified? Is the therapy being monitored for gradual dose reductions unless clinically contraindicated?
6. What specific recommendations can be made to optimize the resident's drug therapy?
7. Are the laboratory results and vital signs being monitored appropriately, and are they available for adequate evaluation of therapy?

The pharmacist identifies and reports any irregularities, including medication discrepancies, errors, and adverse drug reactions in a written report to the attending physician, medical director, and director of nursing, and includes recommendations to help optimize therapy. The physician must respond to recommendations made by the pharmacist in a timely manner. The American Society of Consultant Pharmacists publishes detailed information concerning standards of practice in the LTCF environment.[92]

CASE 107-7

Question 1: As a new consultant pharmacist to a 60-bed, LTCF, several multiple drug use problems become apparent during an initial MRR for D.M., an 82-year-old male who has resided there for the past month. D.M.'s past medical history is significant for HTN, depression, constipation, long-standing mild cognitive impairment that is now worsening, and dizziness. In the nurses' notes, it is documented that D.M. had a fall when getting out of bed last week.

At admission, D.M.'s weight was 165 pounds (74.84 kg), BP 100/60 mm Hg, pulse 85 beats/minute, and temperature 98.6 °F (37 °C). Subsequent vital signs are not recorded systematically into his medical record. Sporadic documentation in the nurses' notes indicates little change from admission values. No laboratory information is available at this time. D.M. has no known allergies.

Current medications include amlodipine 10 mg daily, diltiazem CD 240 mg daily, hydrochlorothiazide 25 mg daily, quetiapine 300 mg daily, lorazepam 0.5 mg every 8 hours as needed for anxiety, docusate sodium 100 mg twice daily, milk of magnesia 30 mL daily, temazepam 15 mg at bedtime, and acetaminophen one to two 325-mg tablets every 4 to 6 hours as needed for pain. D.M. follows a 2-g sodium diet.

D.M. is ambulatory and takes his meals in the facility's dining room. He is not in any acute distress, but the nurses' notes indicate that D.M. is often confused and has dizziness when ambulating. His weight has decreased 4 pounds (1.81 kg) since being admitted.

What should be expected of this LTCF with respect to medication monitoring?

Under the CMS-mandated regulations, the establishment of goals of antihypertensive therapy and monitoring for these goals are required. D.M.'s BP should be measured and documented in his medical record with a signature and date on a regular basis. D.M.'s dizziness, a symptom of orthostatic HTN, may be caused by overtreatment of his HTN as evidenced by his low admission BP. Orthostatic HTN is most common when patients first arise, indicating that this may have been the cause of D.M.'s recent fall.[22] D.M. is being treated with two calcium channel blockers. Discontinuation of one of them may reduce his dizziness and help prevent future falls. Because D.M. is being treated with a diuretic, monitoring should include a chemistry panel for electrolyte abnormalities.

Case 107-7, Question 2: What changes should be made to D.M.'s medication regimen?

In the admission workup, D.M. was described as having a long-standing history of mild cognitive impairment, but subsequent nursing notes suggest that his symptoms of disorientation and confusion worsened quickly after admission. Chronic dementia is not normally characterized by rapid deterioration of mental acuity (see Chapter 108, Geriatric Neurocognitive Disorders). This should raise the suspicion that a reversible factor could be responsible for D.M.'s mental decline. Potentially inappropriate drug use in older adults living in the community and in long-term care is well documented.[93],[94] The cognitive impairment of chronic degenerative dementia can be greatly exaggerated by D.M.'s treatment with lorazepam, temazepam, and quetiapine, especially with higher than recommended dosages.[95],[96] Benzodiazepines may also increase the risk of falls and bone fractures in the geriatric population. The use of antipsychotic agents without a psychiatric diagnosis is only appropriate in nursing homes if the resident's behavior is considered to be a danger to themselves or others (including staff), impairing the patient's daily functioning, interfering with the staff's ability to care for them, or causing distress to the patient (ie, frightening hallucinations).[91] Antipsychotics may be unnecessarily prescribed for anxiety, insomnia, confusion, or failure to conform to the institution's standards for behavior. They carry a black box warning and have been shown to be associated with a 1.7-fold increased risk of all-cause mortality in older adults with dementia compared with nonusers.[97] Antipsychotics are not indicated to treat behaviors in older adults with dementia. Primary reasons for death were HF, sudden cardiac death, or pneumonia. Federal regulations require that these drugs be used for a specified condition, at the lowest possible dosage, and for the shortest possible duration. Regulations also mandate tapering of doses and careful documentation of all clinical assessments that justify the ongoing need for antipsychotics.[91]

In light of the atypical deterioration of D.M.'s cognitive function, the doses of all psychotropic medications should be gradually tapered down to the lowest effective dose and/or discontinued if appropriate. It may not be appropriate to make multiple changes all at once;

however, a plan should be developed to target the medications that are likely responsible for D.M.'s decline in mental status. A baseline assessment of D.M.'s cognitive function and psychiatric status should be performed by a geriatrician, psychiatrist, or clinical psychologist to establish the presence or absence of psychotic behavioral disturbances or depression. If any of these disorders are present, then each should be managed with appropriate nonpharmacologic interventions and drug therapy that includes appropriate therapeutic doses and duration of treatment.

The American Geriatrics Society (AGS) updated the Beers Criteria for Potentially Inappropriate Medication Use in Older Adults in 2019.[24] This evidence-based review outlines medications that may lead to adverse events in all adults older than 65 years. It is intended to be used as a tool to help reduce adverse effects from potentially inappropriate medication. Other helpful tools available include the Screening Tool of Older Persons' potentially inappropriate Prescriptions (STOPP) and Screening Tool to Alert Doctors to Right Treatment (START) criteria.[98] The combined use of these tools along with clinical judgment is meant to guide clinicians in drug selection, help decrease exposure to medications that may increase the risk of adverse drug events, and support the safe medication therapy of older adults.

KEY REFERENCES AND WEBSITES

A full list of references for this chapter can be found at http://thepoint.lww.com/AT12e. The following are the key references and websites for this chapter, with the corresponding reference number in this chapter found in parentheses after the reference.

Geriatric Neurocognitive Disorders

Nicole J. Brandt and Stephanie M. Ozalas

CORE PRINCIPLES		CHAPTER CASES
NEUROCOGNITIVE DISORDERS		
1	Neurocognitive disorder (NCD) is a syndrome that exhibits multiple cognitive deficits that compromise normal social or occupational function. There are numerous etiologies such as Alzheimer disease (AD), dementia with Lewy bodies (DLB), and vascular disease, which require a comprehensive evaluation to define a potential diagnosis.	**Case 108-1 (Question 1)**
NEUROCOGNITIVE DISORDER BECAUSE OF ALZHEIMER DISEASE		
1	AD is a chronic, progressive,	**Case 108-1**

	neurodegenerative disorder that results from neuropathologic findings, such as neurofibrillary tangles and β-amyloid plaques that interfere with cholinergic transmission, as well as other neurochemical changes in the brain.	**(Questions 1–3)**
2	AD has multiple risk factors such as age, family history, Down syndrome, head trauma, hypertension, and mild cognitive impairment; yet, the exact etiology is still unknown.	**Case 108-1 (Question 2)**
3	Treatment for AD is still primarily symptomatic management, not disease altering, and focuses on neurotransmission (eg, cholinergic system).	**Case 108-1 (Question 4)**
4	Cholinesterase inhibitors may be used as monotherapy or in combination with an *N*-methyl-D-aspartate antagonist for patients in the moderate-to-severe stage of AD.	**Case 108-1 (Questions 4–6)**
5	Monitoring for treatment efficacy should focus on cognition, function, and possibly behaviors, whereas treatment toxicity should look for common adverse effects such as gastrointestinal problems with cholinesterase inhibitors.	**Case 108-1 (Question 5–7)**
	NEUROCOGNITIVE DISORDER BECAUSE OF LEWY BODY DISEASE	
1	Has similar neuropathology noted with α-synuclein aggregates found in Lewy	**Case 108-2 (Question 1)**

	bodies and neuritis (α-synucleinopathies), which typically present with parkinsonian findings as well as associated symptoms such as falls and visual hallucinations.	
2	Cholinesterase inhibitors have demonstrated symptomatic benefit in patients with Lewy body dementias yet monitoring for worsening of motor symptoms such as tremor is needed.	**Case 108-2 (Question 2)**
	VASCULAR NEUROCOGNITIVE DISORDERS	
1	Vascular dementia is a broad classification of cognitive disorders caused by vascular disease, and notable multiple risk factors include advancing age, diabetes mellitus, small vessel cerebrovascular disease, hypertension, heart disease, hyperlipidemia, cigarette smoking, and alcohol use.	**Case 108-3 (Questions 1, 2)**
2	Treatment for vascular dementia strives to control the underlying modifiable risk factors owing to limited efficacy and controversial evidence with cholinesterase inhibitors.	**Case 108-3 (Question 3)**
	BEHAVIORAL DISTURBANCES IN DEMENTIA	
1	When evaluating a patient with dementia with behavior disturbances, the first step is to ensure that the	**Case 108-1 (Question 1) Case 108-4 (Question 1)**

	problem is not caused by an unrecognized medical problem or adverse effect of a medication.	
2	Nonpharmacologic strategies are effective for managing many behavior disturbances and should be attempted before using medications to manage behavior.	**Case 108-4 (Questions 1–4)**
3	Delusions and hallucinations are common behaviors in dementia patients, yet the use of antipsychotics for these symptoms is not approved by the U.S. Food and Drug Administration and has been associated with an increased risk of stroke and mortality in this patient population.	**Case 108-4 (Question 2)**
4	Wandering is a safety concern that often does not respond to pharmacologic intervention; instead, other strategies such as environmental modifications are used.	**Case 108-4 (Question 3)**
5	Antidepressants such as selective serotonin reuptake inhibitors have shown promise in addressing depressive symptoms, as well as screaming and irritability.	**Case 108-4 (Question 4)**
6	Caregiver support is essential to maintaining a patient with dementia safely in their home as long as possible.	**Case 108-1 (Questions 3, 5)** **Case 108-4 (Question 5)**

INTRODUCTION

Neurocognitive disorders (NCDs) span a wide range of conditions that exhibit a global decline in cognition. Among the disorders included are delirium, dementia, and several other disorders with various etiologies (eg, head trauma, human immunodeficiency virus [HIV], Huntington disease).[1] Among older adults, dementias are the most commonly encountered diseases and are the focus of this chapter.

GERIATRIC DEMENTIAS

With the continuing growth in the older adult population, the incidence and prevalence of NCDs continue to rise.[2,3] Alzheimer disease (AD) is the most common cause, whereas vascular dementia (VaD), mixed dementia, and dementia with Lewy bodies (DLB) are the next most common dementias. Parkinson disease with dementia (PDD) and frontotemporal dementia (FTD) occur less often.[4] AD is currently the fifth leading cause of death for people ages 65 years and older and the sixth leading cause of death for all people in the United States.[3,5]

Incidence and Prevalence

It is estimated that 6.2 million Americans have AD, including ~17% of people ages 65 years and older and 36% of people ages 85 years and older. Of these, more than 3.6 million are female. Black and Hispanic Americans are disproportionately more likely than older White Americans to have AD or other dementias.[2] The annual incidence of AD in the United States rises from 30 per 1000 among people ages 65 to 74 years to 176 per 1000 for those ages 75 to 84 years, and to 323 per 1000 for those at least 85 years.[6] Worldwide prevalence has been estimated to be as high as 24.3 million, with

8.4 million new cases annually.[7] Projections into the mid-century include a worldwide prevalence of more than 81 million, with cases in undeveloped countries occurring at about three times the rate as in developed countries.[7]

In the United States, the most commonly defined dementia subtype was AD (43.5%), followed by VaD (14.5%), DLB (5.4%), FTD (1.0%), and alcohol-induced dementia (0.7%). The prevalence of other types of diagnosed dementia (eg, Creutzfeldt–Jakob disease and Huntington disease) was 0.2%.[4] Life expectancy after a diagnosis of AD is reduced by as much as 69% for those diagnosed before age 70 and by 39% for those diagnosed after age 90.[8] For individuals diagnosed with DLB, their survival time was almost 20 months shorter than patients with AD.[9] Neither gender difference and age at diagnosis nor cognitive scores (ie, Mini-Mental State Exam [MMSE]) explained differences in survival time between DLB and AD, but patients with DLB had a significantly lower age at death.[9]

The cost of dementia represents a substantial financial burden on society. Based on U.S. estimates from 2020, the annual health care and long-term care payments attributable to dementia care was $52,481 per person. This estimate does not include out-of-pocket expenses (ie, costs other than copayments or coinsurance, health insurance premiums, deductibles), which is estimated to be $11,571 per person. Based on 2020 data, the Alzheimer's Association estimates that the total monetary cost of dementia (in 2021 dollars) is estimated at $355 billion. Medicare is expected to pay ~$239 billion, which is only 67% of the total health care and long-term care payments.[2]

Clinical Diagnosis

Dementia is an NCD that exhibits impaired short- and long-term memory as its most prominent feature. Multiple cognitive deficits that compromise normal social or occupational function must be present before dementia can be diagnosed (**Table 108-1**).[1] Commonly, forgetfulness is the primary patient problem or the first symptom

noted by the family.[10] Family members or others may note several symptoms that should prompt a medical evaluation (**Table 108-2**).[11] Memory loss often accompanies several diseases or disorders in older adults. Therefore, a comprehensive medical history, physical examination, and medication history are essential in excluding systemic illness or medication toxicity as causes of memory loss (**Table 108-3**).[12] Laboratory and other tests to assist in differentiating dementia from other disorders are listed (**Table 108-4**). In patients with AD, test results will generally be normal; evidence of cerebrovascular disease is present in patients with VaD.

Table 108-1

Differentiating Neurocognitive Disorders

Mild (Formerly Mild Cognitive Impairment)	Major (Formerly Dementia)
Neurocognitive Disorder	
Modest cognitive decline from previous (baseline) performance in at least one cognitive domain, including: ▪ Learning and memory ▪ Complex attention ▪ Executive function ▪ Language ▪ Perception and motor ▪ Social cognition The deficits do not impair the capacity to be independent in everyday activities The cognitive symptoms do not occur exclusively during a period of delirium The cognitive deficits are not better explained by depression, schizophrenia, or other mental disorders	Significant cognitive decline from previous (baseline) performance in at least one cognitive domain, including: ▪ Learning and memory ▪ Complex attention ▪ Executive function ▪ Language ▪ Perception and motor ▪ Social cognition The deficits impair the capacity to be independent in everyday activities The cognitive symptoms do not occur exclusively during a period of delirium The cognitive deficits are not better explained by depression, schizophrenia, or other mental disorders
Neurocognitive Disorders Because of Alzheimer Disease	
Criteria for either mild or major NCD are met Insidious onset and gradual progression of impairment	

- Mild: impairment in one cognitive domain
- Major: impairment in at least two cognitive domains

Probable Alzheimer disease (either of the following must be present)

- Alzheimer disease genetic mutation based on family history or genetic testing
- All of the following are present:
  - Decline in memory and learning plus one other cognitive domain
  - Steady and gradual cognitive decline
  - No evidence of another condition that is likely to cause cognitive decline

Possible Alzheimer disease

- Lack of an Alzheimer disease genetic mutation
- All of the following are present:
  - Decline in memory and learning
  - Steady and gradual cognitive decline
  - No evidence of another condition that is likely to cause cognitive decline

Cognitive decline is not better explained by cerebrovascular disease or another condition associated with cognitive decline or neurodegeneration

Vascular Neurocognitive Disorders

Criteria for either mild or major NCD are met

Clinical presentation is consistent with a vascular cause (either of the following is present)

- Onset of cognitive impairment follows a cerebrovascular event or multiple events
- Prominent decline in complex attention and executive function

History, physical exam, and/or neuroimaging indicates cerebrovascular disease as the most likely cause of the cognitive decline

Probable vascular NCD (at least one of the following is present)

- Neuroimaging supports cerebrovascular disease as the cause of the clinical presentation
- The neurocognitive deficit follows at least one cerebrovascular event
- Presence of both clinical and genetic evidence of cerebrovascular disease

Possible vascular NCD

- Clinical criteria are met
- Neuroimaging is not available
- Temporal relationship between the cerebrovascular event(s) and the onset of neurocognitive decline is not established

A systemic disorder (such as depression) or other brain disease do not adequately explain the symptoms

Neurocognitive Disorder With Lewy Bodies (Dementia With Lewy Bodies)

Criteria for either mild or major NCD are met

The onset is insidious, with gradual progression
A combination of the following core and supportive clinical features are present

Core Clinical Features

- Fluctuating cognition accompanied by variable attentiveness and alertness
- Recurrent, well-formed, and detailed visual hallucinations
- REM sleep behavior disorder, which may precede cognitive decline
- One or more spontaneous cardinal features of parkinsonism: these are bradykinesia (defined as slowness of movement and decrement in amplitude or speed), rest tremor, or rigidity

Supportive Clinical Features

- Severe sensitivity to antipsychotic agents; postural instability; repeated falls; syncope or other transient episodes of unresponsiveness; severe autonomic dysfunction (eg, constipation, orthostatic hypotension, urinary incontinence; hypersomnia; hyposmia; hallucinations in other modalities; systematized delusions; apathy, anxiety, and depression)

Indicative Biomarkers

- Reduced dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET Abnormal (low uptake) 123-iodine-MIBG myocardial scintigraphy
- Polysomnographic confirmation of REM sleep without atonia

Supportive Biomarkers

- Relative preservation of medial temporal lobe structures on CT/MRI scan
- Generalized low uptake on SPECT/PET perfusion/metabolism scan with reduced occipital activity 6 the cingulate island sign on FDG-PET imaging
- Prominent posterior slow-wave activity on EEG with periodic fluctuations in the pre-alpha/theta range

Probable DLB Can Be Diagnosed If:

a. Two or more core clinical features of DLB are present, with or without the presence of indicative biomarkers, or
b. Only one core clinical feature is present, but with one or more indicative biomarkers
c. Probable DLB should not be diagnosed based on biomarkers alone

Possible DLB Can Be Diagnosed If:

a. Only one core clinical feature of DLB is present, with no indicative biomarker evidence, or
b. One or more indicative biomarkers is present, but there are no core clinical features.
c. Cognitive decline is not better explained by cerebrovascular disease, Parkinson disease dementia, or another condition associated with cognitive decline or neurodegeneration Cognitive decline generally occurs first in NCD with Lewy bodies, and motor symptoms occur first in Parkinson disease dementia

CT/MRI, computed tomography/magnetic resonance imaging; DLB, dementia with Lewy bodies; EEG, electroencephalogram; NCD, neurocognitive disorder; PET, positron emission tomography; REM, rapid eye movement; SPECT, single-photon emission computed tomography.

Table 108-2
Symptoms Suggesting Dementia

Neurocognitive Domain	Symptom	Evidence
Learning and memory	Difficulty learning or retaining new information	Repeats questions; difficulty remembering recent conversations, events, etc.; loses items
Execution function	Unable to handle complex tasks	Cannot complete tasks that require multiple steps (eg, difficulty following a shopping list); unable to make complex decisions
Complex attention	Divided/selected attention; processing speed	Inability to continue tasks for long periods of time; slower response time
Perceptual-motor function	Impaired spatial orientation and abilities	Gets lost in familiar places; difficulty with driving
Language	Language deficits	Problems finding appropriate words (eg, difficulty with naming common objects)
Social cognition	Behavior changes	Changes in personality; suspiciousness; inappropriate social behavior

Table 108-3
Causes of Dementia Symptoms

Modifiable Risk Factors	Nonmodifiable Risk Factors
Disease states Deficiency states ▪ Vitamin B_{12} ▪ Folate ▪ Iron Delirium Amnestic syndrome (eg, isolated memory impairment) Brain abscess Normal pressure hydrocephalus Infections Medications Anticholinergic agents Antihistamines Anti-infectives Corticosteroids H_2-receptor antagonists Narcotic analgesics Nonsteroidal anti-inflammatory agents Sedative hypnotics and anxiolytics Skeletal muscle relaxants	Disease states Adjustment disorder (eg, inability to adjust to retirement) Cardiovascular disease Arrhythmia Heart failure Vascular occlusion Depression Intracranial causes Cerebrovascular accident Subdural hematoma Tumor Metabolic disorders ▪ Hypo-/hypercortisolism ▪ Hypo-/hyperaldosteronism ▪ Hypo-/hyperglycemia ▪ Hypo-/hyperthyroidism Medications Anticonvulsants Antidepressants Antineoplastic agents Antipsychotic agents Cardiovascular agents ▪ Antiarrhythmics ▪ Antihypertensives Immunosuppressants

Brain imaging, such as computed tomography (CT) scan or magnetic resonance imaging (MRI), can be useful in establishing the presence of dementia, but neither is diagnostic. A CT scan is useful when a space-occupying lesion, such as a tumor, is suspected as a

possible cause. An MRI scan is capable of identifying small infarcts or small vessel ischemic changes, such as those found in some forms of VaD, and atrophy of subcortical structures such as the brainstem.[12]

Several simple tests, including the Mini-Cognitive Assessment Instrument (Mini-Cog),[13] the Montreal Cognitive Assessment (MoCA),[14] and the St. Louis University Mental Status (SLUMS) exam,[15] are appropriate for initial screening of people with suspected cognitive impairment. The Folstein MMSE also can be used; however, it is less sensitive than others for dementia and now is proprietary.[16] These tests rapidly assess multiple domains, typically including orientation, registration, attention and calculation, recall, and language. Patients with dementia exhibit deficits in multiple areas. Those who score below the normal range on the MMSE or other screens or those who exhibit symptoms characteristic of dementia receive further testing. All screening tests are subject to limitations. Therefore, additional psychometric testing is often ordered to further establish the presence and type of dementia.[11,17]

Dementias may be classified as cortical or subcortical according to the areas of the brain preferentially affected by the disorder. AD, a typical cortical dementia, disrupts the cerebral cortex. Patients with cortical dementias display impaired language rather than impaired speech, a learning deficit (amnesia), reduced higher cortical functions (eg, inability to perform calculations, poor judgment), and an indifferent or disinhibited affect. Subcortical dementias such as VaD and PDD primarily affect the basal ganglia, thalamus, and brainstem. Deficits include abnormal motor function, disrupted speech patterns rather than language difficulties, forgetfulness (impaired recall), slowed cognitive function, and an apathetic or depressed affect.[11]

ALZHEIMER DISEASE

Etiology

A definitive cause for AD has yet to be determined. Several risk factors, however, have been identified. Advancing age is the primary risk factor for AD; other risks include family history, head trauma, metabolic syndrome, diabetes, hypertension (HTN), and cardiovascular disease.[2,18–21] Genetics play a significant role in the development of AD. The high familial occurrence of AD has been linked to autosomal-dominant traits on chromosomes 21, 14, and 1.[22,23] A gene that encodes for amyloid precursor protein (APP), a normal protein, is located on chromosome 21. A defect on chromosome 14 has been identified as the locus for the presenilin-1 gene, which codes for an inherited form of AD. The presenilin-2 gene, located on chromosome 1, also codes for an inherited form. Despite a strong genetic link in some pedigrees, the great majority of AD cases are sporadic.[22,24] The more common sporadic form appears to be linked to a susceptibility gene, apolipoprotein E, which occurs in three isoforms.[25] APP, a normal protein found throughout the body, maps on chromosome 21 and plays a pivotal role in AD neuropathology. Because of overproduction or transcription errors, an abnormal subunit (ie, β-amyloid) is produced.[23] Mutations on chromosomes 14 (presenilin-1 gene) and 1 (presenilin-2 gene) and the presence of apolipoprotein E4 allele code for alterations in the processing of APP. The abnormal cleavage of APP produces a 42–amino acid form of β-amyloid (Aβ) that demonstrates a higher toxicity than other amyloid forms.[24]

Table 108-4
Dementia Screening Tests

Test	Rationale for Testing
Complete blood count with sedimentation rate	Anemic anoxia, infection, neoplasms
Metabolic Screen	
Serum electrolytes	Hypernatremia, hyponatremia; renal function
Blood urea nitrogen,	Renal function

creatinine	
Bilirubin	Hepatic dysfunction (eg, portal systemic encephalopathy, hepatocerebral degeneration)
Thyroid function	Hypothyroidism, hyperthyroidism
Iron, vitamin B_{12}, folate, vitamin D	Deficiency states (vitamin B_{12}, folate neuropathies, vitamin D deficiency), anemias
Stool occult blood	Blood loss, anemia
HIV and RPR	Infection
Urinalysis	Infection, proteinuria
Chest roentgenogram	Neoplasms, infection, airway disease (anoxia)
Electrocardiogram	Cardiac disease (stagnant anoxia)
Brain scan	Cerebral tumors, cerebrovascular disease
Mental status testing	General cognitive screen
Depression testing	Depression, pseudodementia

RPR, rapid plasma reagin.

Apolipoprotein E (ApoE), a protein that is involved in cholesterol and phospholipid metabolism, plays a role in the development of sporadic, late-onset AD. The ApoE gene possesses three alleles: E2, E3, and E4. The E3 allele is most common, the E2 allele appears to be protective against AD, and the E4 allele increases the risk for AD.[24] The presence of ApoE4, the protein encoded by the E4 allele, appears to increase the deposition of Aβ and promote its change to a more pathologic configuration.[24] The presence of one or two copies of ApoE4 increases the risk of developing AD twofold or fivefold, respectively.[25] Aβ, which differs from amyloid protein found in other regions of the body, appears to contribute to neuronal death through a combination of apoptosis, a direct toxic effect, and an increased risk for damage owing to oxidative and metabolic stresses.[22],[24]

Neuropathology

Although brain atrophy is the most obvious finding among patients with Alzheimer-type dementia, it is not diagnostic for AD or other dementias because some degree of atrophy accompanies normal aging. Atrophic changes induced by AD are found primarily in the temporal, parietal, and frontal areas of the brain; the occipital region, primary motor cortex, and somatosensory areas are generally unaffected (**Fig. 108-1**).[11]

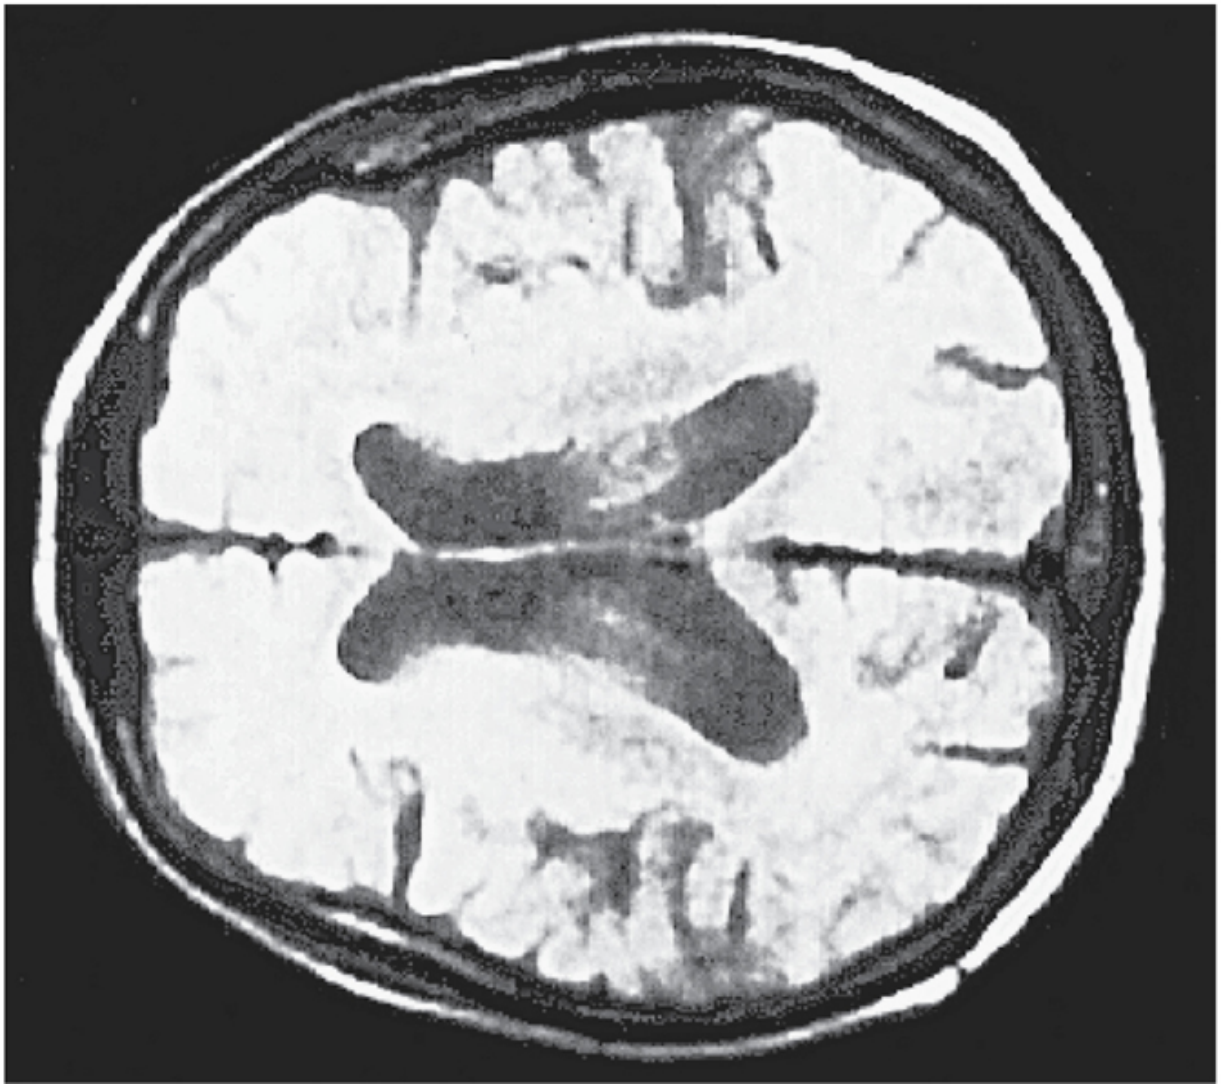

Figure 108-1 Alzheimer disease: magnetic resonance imaging scan. Ventricles are enlarged, and there is generalized atrophy, with greater atrophy present near the temporal areas.

Neuronal changes in the cerebral cortex associated with AD include neurofibrillary tangles (NFTs), neuritic plaques, amyloid angiopathy, and granulovacuolar degeneration. These changes lead to loss of neurons and synapses (**Fig. 108-2**).[22] NFTs are found primarily in the pyramidal regions of the neocortex, hippocampus, and amygdala, but they are also noted in areas of the brainstem and locus coeruleus.[23],[24] NFTs are composed of paired helical filaments, combinations of fibrils with a characteristic width and contour, containing a tau protein with an abnormal pattern of phosphate deposition. They are highly immunoreactive and are most likely to form in large pyramidal neurons.

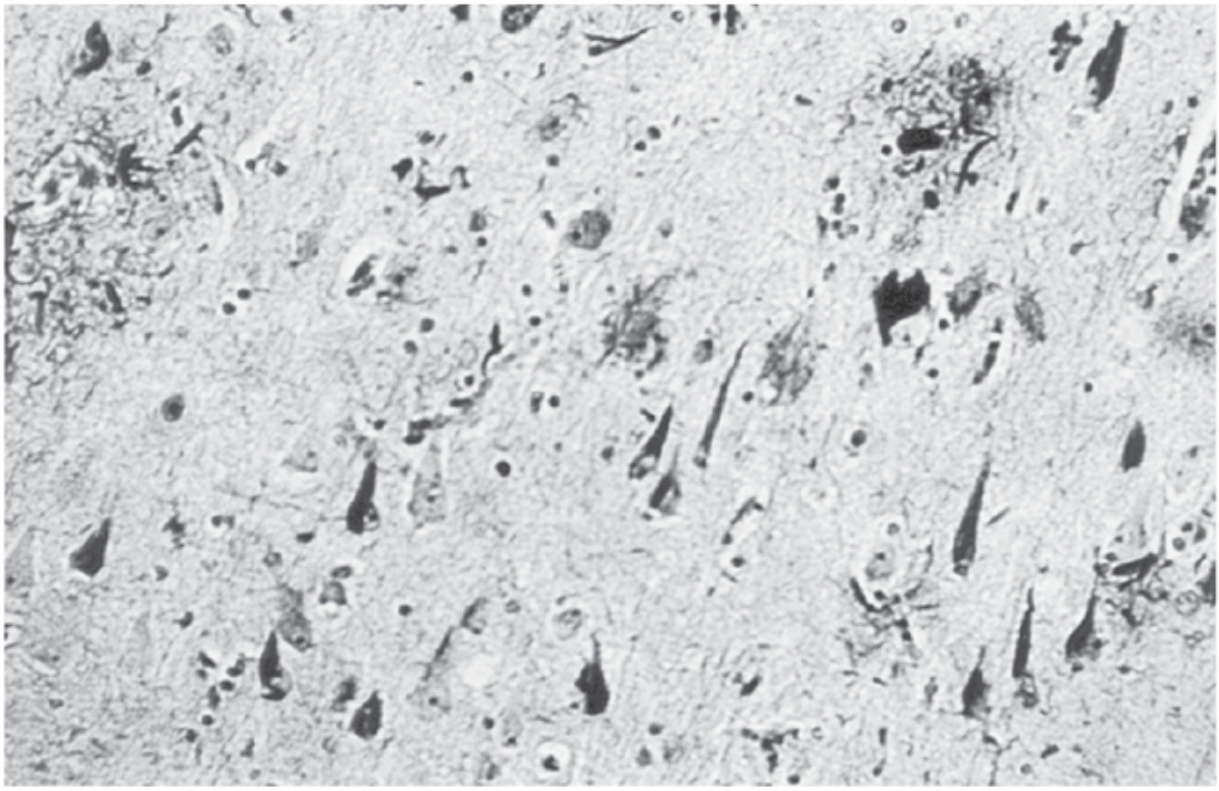

Figure 108-2 Numerous plaques (large, round bodies) and tangles (tear-shaped bodies) are found throughout the cortex in Alzheimer-type dementia.

Neuritic plaques are spherical bodies of tissue composed of granular deposits and remnants of neuronal processes.[26] The typical neuritic plaques of AD are spherical structures that exhibit a three-

tiered structure: a central amyloid core, a middle region of swollen axons and dendrites, and an outer zone containing degenerating neuritic processes.[23] Plaques contain APP, which can be cleaved by a defective metabolic process to form Aβ.[22] In addition to Aβ, plaques contain protein, ApoE, and acute-phase inflammatory proteins such as α_1-chymotrypsin and α_2-macroglobulin.[22] The deposition of amyloid in neuritic plaques correlates with the severity of AD, and the density of cortical plaques is associated with decreased choline acetyltransferase and the severity of cognitive impairment.[27] Aβ has been identified in plaques associated with Down syndrome and in both familial and sporadic forms of dementia of the Alzheimer type.[27] The pathologic process of AD development may begin as early as 20 to 30 years before any disease symptoms appear.[23],[24]

Granulovacuolar degeneration is the other major histologic finding in AD. It consists of clusters of intracytoplasmic vacuoles that contain tiny granules. The vacuoles appear to be specifically located in the pyramidal neurons of the hippocampus.[5],[15],[26] The loss of cortical neurons that originate in the nucleus basalis and project into the cerebral cortex is the most significant histopathologic consequence of AD.[24] Cell loss, granulovacuolar degeneration, and neurons with NFTs are concentrated in this area.[22]

Accompanying these changes are decreased concentrations of several neurotransmitters and enzymes. Choline acetyltransferase levels are reduced 60% to 90% in the cortical and hippocampal regions.[28] Acetylcholine and acetylcholinesterase (AChE) are also decreased, whereas muscarinic receptors in the cortex and hippocampus remain at normal levels or are moderately decreased. Nicotinic receptor proteins are also reduced in patients with Alzheimer-type dementia when compared with age-matched controls. Decreased choline acetyltransferase activity has been correlated with plaque density and disease severity. Cortical synapse loss, especially in the midfrontal region, is associated with disease severity.[24],[28]

Changes affecting AChE have significant implications for the management of AD symptoms. Many isoforms of AChE have been identified; they possess identical amino acid sequences but display different posttranslational modifications, predominate at diverse anatomical and microanatomical locations, and function in different ways. The predominant form of AChE in the cortical and hippocampal regions of humans is G4, a tetrameric form that is membrane bound. The monomeric form, G1, is found in a much lower concentration. There is a selective loss of the G4 form in patients with AD, allowing the G1 form to assume greater importance.[29] Although cholinergic activity is most significantly affected by Alzheimer-type dementia, other neurochemical systems are also altered. Norepinephrine, serotonin, and γ-aminobutyric acid receptors are affected.[23],[26]

Clinical Presentation and Diagnosis

CASE 108-1

Question 1: P.Y. is a 75-year-old male who is accompanied by his wife for a memory assessment. During the interview, the patient notes that memory issues started about 6 to 12 months ago but noticed that recently he has been "getting distracted" with driving and hit another car because he forgot to change gears when he was parking the car. The wife notes he frequently misplaces his car keys and wallet, as well as forgets to pick up all the groceries despite having a list. At first, the wife thought that he might have some visual impairment, but a recent ophthalmic exam revealed no significant deficits.

P.Y.'s medical history is significant for allergic rhinitis, glaucoma, and HTN. He has been currently prescribed loratadine 10 mg at bedtime for allergic rhinitis, latanoprost 0.005% 1 drop in each eye at bedtime for glaucoma, and amlodipine 10 mg daily for HTN. His family history is negative for stroke and positive for heart disease, and his mother died of a myocardial infarction at age 79. The wife admits that his father had AD and was diagnosed in his late 70s as well. He died at the age of 82 because of complications with his AD in a nursing home and his wife witnessed his dramatic decline from the AD, which worries him.

Physical examination reveals a pleasant, well-groomed male who is in good health oriented to person and place but not time. His blood pressure (BP) is 132/72 mm Hg supine and 146/84 mm Hg standing, with pulse rates of 58

beats/minute and 66 beats/minute, respectively. The rest of the physical examination was within normal limits.

The MoCA was 20/30, with errors in orientation (wrong date), attention, visuospatial, memory and delayed recall, as well as language.

What additional evaluation steps should be considered for P.Y.?

Before any conclusions can be reached, potentially reversible causes for P.Y.'s impaired cognition must be evaluated. However, he does display several trigger symptoms associated with dementia (see Table 108-2), including his recent car accident and difficulty following complex instructions coupled with memory impairment impacting day-to-day function.

Several systemic diseases and other disorders can cause cognitive impairment, as shown in Table 108-3. P.Y. should undergo a battery of laboratory tests to rule out anemia, cardiac and renal disease, thyroid abnormalities, and tumors. In addition, he should receive thorough neuropsychological testing, including depression screening and more in-depth assessment of his cognitive function. The testing should be conducted by clinicians who are skilled in cognitive assessment, as educational and cultural factors can influence an individual's performance on these tests.[17] A key is to better understand where he is functioning on the disease continuum. Based on tools that assess episodic memory, both immediate and delayed recall are valuable. Decline in executive functions may also flag incident AD dementia; by contrast, change in information processing speed/attention seems less informative.[30] Overall, the clinical continuum includes trajectories for both cognition and function. Cognition includes trajectories of episodic memory, executive function, and verbal fluency, whereas function includes trajectories of both basic and complex activities of daily living (ADLs). It appears cognitive impairment precedes and predicts functional impairment.[31]

Case 108-1, Question 2: P.Y. is referred by his physician for additional testing. Laboratory tests performed include renal and liver chemistries, thyroid function tests, vitamin B_{12} and folate levels, syphilis and HIV tests, complete blood cell count with sedimentation rate, and urinalysis. All results were normal,

except for a borderline elevated TSH (6.54 mU/L) and T4 within normal limits. Chest radiograph and electrocardiogram were normal. Neurologic examination revealed no deficits. Depression testing revealed a mildly anxious individual who was not depressed, just worried about his future. What is the most probable diagnosis for P.Y.?

P.Y.'s MoCA score of 20/30 is consistent with mild neurocognitive impairment or early dementia as evidenced by errors in orientation, visuospatial, recall, and language.[15] Secondary medical causes of cognitive impairment can be eliminated by P.Y.'s generally normal physical examination and laboratory test results. MRI or CT scanning may be useful in many cases to help eliminate brain pathology, such as stroke.[25] A positron emission tomography (PET) scan or a single-photon emission computed tomography (SPECT) scan may be useful to help locate specific areas of pathology and assist with a differential diagnosis, but are not required.[25] Secondary psychiatric causes for P.Y.'s decline can also be discounted. Although he is sad and anxious, the absence of alterations in appetite or sleep patterns, absence of suicidal thoughts, and the results of psychologic testing indicate P.Y. is not depressed. He is fully conscious, alert, and oriented to place and person. He exhibits no psychotic behavior and no evidence of delirium.

P.Y.'s slowly progressive decline and its impact on his social and occupational function (forgetting groceries, impaired driving ability), normal physical examination and laboratory findings, and family history meet the *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition (DSM-V) criteria for minor neurocognitive impairment (see Table 108-1). His history and course to date satisfy the criteria for AD and do not indicate a likely alternative explanation for his condition. Thus, P.Y. can be classified as probable AD.[17]

Case 108-1, Question 3: P.Y.'s children are very concerned about the family history of dementia. They ask whether there are any tests they should receive at this time to determine their risk. What should they be told?

Although there is a strong genetic association with AD, such instances account for a small minority of cases.[23] There is no apparent family history of Down syndrome. Mutations in the presenilin-1 and presenilin-2 genes are associated with only a small fraction of AD cases.[23] The role of biomarkers, which once was considered appropriate only for research-related purposes,[32] is increasingly being integrated into clinical decision-making. CSF Aβ42, total tau (t-tau), and phosphorylated tau (p-tau) biomarkers and amyloid PET have been the most widely studied.[33],[34] However, the challenges with cost, standardization, accessibility, and incorporation of biomarker findings into patient treatment plans have limited their utility.

Prognosis

Case 108-1, Question 4: What is the likely prognosis for P.Y.?

AD follows a predictable course that may progress over the course of 10 years or more.[2],[8] Two common rating scales for dementia are the Global Deterioration Scale and the Clinical Dementia Rating Scale. According to the Global Deterioration Scale (**Table 108-5**), P.Y.'s impaired social functioning, anxiety, and objective cognitive decline as well as his continued ability to concentrate and perform some complex skills, combined with his preserved affect and social interaction, are consistent with the features of stage three dementia of the Alzheimer type. This stage of AD is generally associated with a period of mild cognitive decline.[35] The more general Clinical Dementia Rating Scale also places P.Y. in the category of mild NCD.[36] Clinical diagnoses of AD using clinically appropriate criteria and assessment methods for probable AD have a sensitivity of up to 90% when compared with autopsy-confirmed cases.[1],[31],[34]

Table 108-5
Stages of Dementia of the Alzheimer Type

Stage of Cognitive Decline	Features
No cognitive decline	Normal cognitive state
Very mild cognitive decline	Forgetfulness, subjective reports only; no objective decline
Mild cognitive decline	Objective decline through psychiatric testing; work and social impairment; mild anxiety and denial
Moderate cognitive decline	Concentration, complex skills decline; flat affect and withdrawal
Moderately severe cognitive decline	Early dementia; difficulty in interactions; unable to recall or recognize people or places
Severe cognitive decline	Requires assistance with bathing, toileting; behavioral symptoms present (agitation, delusions, aggressive behavior)
Very severe cognitive decline	Loss of psychomotor skills and verbal abilities; incontinence; total dependence

Because of technologic advances, it is possible to diagnose dementia earlier and to keep patients alive into the final stages of the disease.[35] The early diagnosis of AD in P.Y. will allow his condition to be followed closely. To ensure the most favorable outcome, P.Y. should receive a thorough assessment beyond his dementia. This should include evaluation of his daily function (ie, ability for self-care), comorbid medical conditions, medications, living arrangements, safety, and potential for abuse and neglect. Attention also should be given to P.Y.'s caregivers and support system.[36] He should be reassessed every 6 months to both document disease progression and ensure that he is receiving the most appropriate

care. At some point, care at home may become unrealistic. At that time, P.Y. should be moved into a sheltered environment (eg, residential-care facility, assisted-living facility, nursing home) before suffering an injury caused by his poor judgment (eg, failing to dress properly for the weather, falling). In the later stages, interventions ranging from tube feedings to life support may prolong life, yet prove to be controversial.[37] Death in the late stage of AD is commonly associated with the development of infections such as pneumonia, urinary tract infections, or decubitus ulcers.

Treatment

If possible, maintaining independence is an important goal in treating a patient with dementia. Keeping patients in familiar surroundings allows them to function without the added burden of having to attempt to adapt to a strange environment. Concurrent diseases and many medications can reduce function and increase cognitive impairment in patients with dementia.

Case 108-1, Question 5: What is an appropriate initial treatment strategy for P.Y.?

P.Y.'s family needs to be educated about what to expect as his dementia progresses. They should be referred to the Alzheimer's Association (www.alz.org) and to the Family Caregiver Alliance (www.caregiver.org). Both organizations provide a wealth of information and community resources, including caregiver support groups. They also should be encouraged to enroll in the MedicAlert + Alzheimer's Association Safe Return program, which provides 24-hour nationwide emergency response for people with dementia who wander or suffer a medical emergency. P.Y.'s family should include him in any advance planning, seek legal advice regarding advance directives and durable power of attorney for health care and finance, and conduct estate planning to avoid having to perform these tasks when P.Y. is no longer competent to participate.[38]

Currently, two main classes of medications are used in the treatment of AD, cholinesterase inhibitors (ChEIs) and *N*-methyl-D-aspartate (NMDA) receptor antagonists.[39] They are pharmacologically distinct and can be prescribed concurrently in patients in the moderate-to-severe stages of the illness. ChEIs act on inhibiting AChE, an enzyme directly involved in the destruction of acetylcholine, leading to increased concentrations in the nucleus basalis of Meynert in the brain and hence ameliorating the cognitive and functional aspects of AD. Cholinesterase inhibitors have been shown to improve cognition and function and delay symptom progression in people with dementia; however, benefits are limited. Cholinergic-related effects, particularly in the gastrointestinal (GI) tract, are the most common adverse effects caused by all of the agents.[40]

The U.S. Food and Drug Administration (FDA) approved aducanumab-avwa (ADUHELM), an Aβ-directed antibody, on June 7, 2021, under an accelerated approval pathway for the treatment of AD. Treatment with aducanumab-avwa is indicated in patients with mild cognitive impairment or mild dementia stage of disease, the population in which treatment was initiated in clinical trials.[41] There are no safety or effectiveness data on initiating treatment at earlier or later stages of the disease than were studied. Approval was based on a surrogate outcome of β-amyloid plaque reduction (measured by PET Aβ SUVR), a known pathophysiologic feature of AD, while peer-reviewed publications have yet to be published.[42] Continued approval is contingent on clinical trials confirming clinical benefit, with the phase 4 trial to be completed by August 2029.

DONEPEZIL

Donepezil is a piperidine derivative that is somewhat selective for central AChE. It reversibly inhibits cholinesterase activity. Donepezil is highly bioavailable and exhibits a long half-life, allowing it to be given as a single daily dose. It is highly protein bound, primarily to albumin.[43]

Donepezil may improve cognition, global function, and behavioral symptoms across all stages (mild, moderate, and severe) of AD. In a multicenter, double-blind, placebo-controlled trial, subjects with mild-to-moderately severe AD improved during a 12-week treatment period.[44] Subjects taking 10 mg of donepezil at bedtime improved their cognitive function as measured by the Alzheimer's Disease Assessment Scale-Cognitive Subscale (ADAS-Cog) and their overall function as measured by the Clinician's Interview-Based Impression of Change with caregiver input (CIBIC-Plus).[45],[46] A 24-week multicenter, placebo-controlled trial using dosages of 5 mg/day and 10 mg/day demonstrated similar results. Both 5- and 10-mg doses were superior to placebo; adverse effects were less common with the 5-mg dose.[47] A long-term, open-label follow-up study to these trials demonstrated that donepezil effects may persist for almost 3 years.[48] Interruption or discontinuation of donepezil treatment was followed by a return of cognition and function to baseline or below.

Donepezil is also indicated for the severe stage of AD. A 6-month, double-blind, parallel-group, placebo-controlled study in patients with severe AD (MMSE 1–10) demonstrated an improvement in the Severe Impairment Battery[49] and Modified Alzheimer's Disease Cooperative Study ADLs inventory for severe AD. The domains that showed a significant improvement versus placebo were language, praxis, visuospatial, bowel/bladder function, and ability to get dressed. There were no differences noted in the neuropsychiatric inventory for behavioral issues associated with dementia.[50] A 23-mg dose of donepezil was approved for patients in the moderate-to-severe stages of AD. Small improvements were seen in the Severe Impairment Battery, and there was no improvement in the CIBIC-Plus when compared with the 10-mg dose. More than 30% of the high-dose group and nearly 18% of the low-dose group failed to complete the 24-week trial.[51]

The most common adverse effects of donepezil are associated with cholinergic activity. They tend to be mild to moderate in nature and resolve with stabilization of the dose.[44],[47] In a 144-week extension trial of donepezil, the most frequently encountered adverse effects were nausea, diarrhea, and headache.[48] In clinical

trials, however, adverse effects were the primary reason for withdrawal from studies, with an overall dropout rate of 29% in the treatment groups.[42]

RIVASTIGMINE

Rivastigmine is a carbamate derivative that inhibits both AChE and butyrylcholinesterase (BChE) activity. BChE provides an alternative pathway for acetylcholine metabolism. Rivastigmine inhibits the activity of both cholinesterases, primarily in the central nervous system.[52] Its AChE inhibition is greater for the G1 as compared with the G4 form.[30] The drug binds to the esteratic sites of the AChE and BChE molecules and slowly dissociates. Because of this, it is often referred to as a "pseudoirreversible" inhibitor.[53] Rivastigmine's biologic half-life is ~1 hour, but because its slow dissociation extends its activity for at least 10 hours, it can be dosed twice daily. Rivastigmine is bound ~40% to serum proteins and is metabolized via hydrolysis to renally excreted inactive compounds.[52] Rivastigmine absorption is nearly complete, but because it undergoes a significant first-pass effect, the resultant bioavailability is ~36%.

In two large clinical trials conducted in patients with mild-to-moderately severe AD, rivastigmine improved cognition, the ability to perform daily activities, and global function over the course of 24 weeks.[53],[54] In each multicenter, double-blind, placebo-controlled trial, subjects were randomly assigned to receive placebo, low-dose (1–4 mg/day) or high-dose (6–12 mg/day) rivastigmine in two divided doses during a 26-week period. In one study, subjects in both rivastigmine groups demonstrated statistically significant improvement after 26 weeks on the ADAS-Cog and CIBIC-Plus scales.[53] In the other trial, only those subjects taking 6 to 12 mg/day improved on the same scales.[54] An open-label extension study that included subjects from both previous studies found that subjects taking 6 to 12 mg/day of rivastigmine had significantly better cognitive function after 1 year than did subjects who had originally received placebo.[55]

Adverse effects typically include nausea, vomiting, diarrhea, and other cholinergic-mediated GI effects.[52] They are most common when rivastigmine is taken on an empty stomach or when the dose escalation is too rapid. Headache, dizziness, and fatigue are also common adverse effects. Increasing the dose by 1.5 mg twice daily at 4-week intervals increases drug tolerability and reduces the frequency and severity of GI side effects. Adverse effect severity appears to be less problematic with a transdermal formulation that delivers 4.6 or 9.5 mg/24 hours, which correspond to 6- and 12-mg daily doses of the oral formulation.[56] The maintenance dose is generally 9.5 to 13.3/day. In patients with moderate-to-severe AD, the maintenance dose is 13.3 mg/day. If treatment is interrupted for at least 3 days, the lowest dosing should be restarted.

GALANTAMINE

Like other agents used to treat AD, galantamine enhances cholinergic activity by inhibiting AChE. However, it also stimulates nicotinic receptors (α-7-nicotinic receptor agonist) at a site distinct from that stimulated by acetylcholine, an action that does not rely on the presence of acetylcholine. This action is referred to as allosteric modulation.[30] Galantamine is rapidly and completely absorbed, reaches peak serum levels in <2 hours, and has a half-life of ~5 hours. It exhibits low protein binding and has a large volume of distribution. Galantamine is metabolized primarily by cytochrome P-450 (CYP) isoenzymes, CYP2D6 and CYP3A4, and is eliminated in the urine.[57]

Clinical trials have shown galantamine to be effective for the symptomatic treatment of mild-to-moderate AD. Doses of 16 and 24 mg/day produced clinically meaningful improvement in ADAS-Cog and CIBIC-Plus scores during a 5-month, randomized, placebo-controlled trial.[58] A similar trial was conducted in Europe and Canada that evaluated patients for 6 months used doses of 24 and 32 mg/day. Both doses were more effective than placebo, but patients in the 32-mg/day group exhibited more adverse effects.[59] A 6-month, open-label extension trial showed that patients treated with

galantamine 24 mg/day maintained ADAS-Cog scores throughout the entire 12 months of the study.[59]

As with the other ChEIs, cholinergic effects in the GI tract are the most commonly encountered adverse effects. Nausea, diarrhea, vomiting, and anorexia were the most frequent events encountered during clinical trials.[30],[42] They were typically present during the dose escalation phases of the studies. A dose titration interval of 4 weeks reduces the severity of adverse effects and increases tolerability.

CASE 108-1, QUESTION 6: What treatment should be instituted for P.Y., and how should therapy be monitored?

P.Y. is in the mild stage of the disease, so a ChEI is an appropriate choice.[39] It is unlikely that a ChEI will produce a dramatic or long-lasting improvement in P.Y.'s cognitive abilities. Systematic reviews of ChEI therapy have consistently concluded that these agents provide modest benefits, at best, in the majority of patients.[40],[60] Treatment, however, may slow his cognitive decline, help maintain his ability to care for himself for 1 year or more, and reduce the risk for nursing facility placement for as much as 2 years.[57] Beneficial effects may occur for as long as 3 years, and patients who start therapy earlier may experience greater benefit than those who delay treatment.[58],[59] The choice of drug is based on the agent most likely to produce a positive response with the fewest adverse effects. Ease of adherence must also be considered. All agents exhibit similar adverse effect profiles. Rivastigmine may be less prone to drug interactions because of its metabolic pathway.[52] It is also available as a transdermal patch that is applied daily. Whereas the oral formulation of rivastigmine requires an initial, nontherapeutic titration dose to reduce the severity of adverse effects, the initial transdermal dosage is therapeutic.[56] Donepezil and galantamine extended release can be given as a single daily dose and are available as generic equivalents. They can be given at bedtime, which may make cholinergic side effects less troublesome.

Donepezil may be an appropriate agent for P.Y. He should receive donepezil 5 mg at bedtime. He should be monitored for cholinergic side effects (particularly nausea and diarrhea, insomnia, headache, and dizziness, the adverse effects most commonly reported in clinical trials).[44,47] Additionally, he should be monitored for bradycardia because of his preexisting low heart rate. Patients who received moderate-to-high doses of donepezil showed an increased incidence and greater risk of bradycardia, especially those with risk factors (eg, cardiovascular disease, concomitant use of β-blockers, calcium channel blockers, antiarrhythmics).[61] His family and physician should look for improvements in his memory, orientation, and ability to concentrate on complex tasks, such as managing finances. He may also become less irritable.

Case 108-1, Question 7: His family was wondering what other options could be employed to address the progression of dementia?

After 1 month, his physician should assess him for adverse effects. If he has not improved noticeably after 4 to 6 weeks, the dose of donepezil may be increased to 10 mg at bedtime. If his condition does not respond to donepezil after a 6-month trial or he is unable to tolerate the donepezil, it is reasonable to switch P.Y. to another ChEI. Both rivastigmine and galantamine have additional mechanisms of action that might prove beneficial. Rivastigmine is started at a dose of 1.5 mg twice daily with meals to slow absorption and improve tolerability. The dose may be increased at 4-week intervals by 1.5 mg twice daily, up to the maximal dose of 6 mg twice daily; however, the transdermal formulation is better tolerated and may be preferable by avoiding a titration phase. Galantamine can be started at 4 mg twice daily or 8 mg daily (extended release) and increased every 4 weeks by 8 mg, up to a maximal dose of 24 mg daily. As with oral rivastigmine, the initial dose is not therapeutic.[57] Taking galantamine with meals may improve tolerability of GI effects. If a trial of a second agent does not improve or stabilize a patient's condition, there is no value in attempting a third agent. P.Y. should

have routine reassessment of his daily function, cognition, and behavior at 6-month intervals.[62–64] Close attention also must be paid to his other medical conditions, and his family should be provided ongoing support, such as through an AD caregiver support group.

MEMANTINE

As P.Y.'s AD progresses, there are two treatment options that can be tried. One option is to further titrate up the donepezil dose to 23 mg/day as mentioned above with some limited clinical efficacy.[48] Another option is to use an NMDA antagonist, which has been shown to reduce the release of glutamate in the central nervous system that can lead to excitotoxic reactions and cell death in AD and other neurodegenerative disorders.[65] Memantine is a noncompetitive NMDA receptor antagonist with moderate affinity and voltage-dependent binding. It is completely absorbed after oral administration, reaches peak serum concentrations in 3 to 8 hours, and is moderately protein bound.

Multiple clinical trials have evaluated memantine in subjects with moderate-to-severe AD. A dose of 10 mg/day for 12 weeks increased functional ability (eg, dressing, toileting, participating in group activities) and reduced care dependence compared with placebo.[65] A 28-week trial using a dose of 20 mg/day improved CIBIC-Plus scores, ADLs, and global function compared with placebo.[66] Overall, the benefits of memantine are modest.[67] The combined use of memantine and a ChEI has been shown to be superior to a ChEI alone by improving daily function in individuals with moderate-to-severe dementia.[68–70] Common adverse effects include diarrhea, insomnia, dizziness, headache, and hallucinations.[65] Memantine has also been studied in patients with mild-to-moderate AD with 2000 IU/d of α-tocopherol (vitamin E) compared with placebo.[71] The α-tocopherol resulted in slower functional decline, whereas there were no significant differences in the groups receiving memantine alone or memantine plus α-tocopherol. P.Y. should be started on memantine 5 mg daily, with the dosage increased in weekly intervals by 5 mg/day, up to a dose of 10

mg twice daily.[65] As an alternative, he can be started on the extended-release formulation given in weekly escalating doses of 7, 14, 21, and 28 mg daily.

LEWY BODY DEMENTIAS

Etiology

Lewy bodies are hyaline-containing inclusion bodies typically found in people with Parkinson disease. Recently, attention has been given to distinguish DLB and PDD to help further research.[72] It is known that up to 25% of patients with dementia have Lewy bodies in the brainstem and cortex (particularly in the limbic and paralimbic cortices and frontal and temporal lobes).[73] Concentrations are found in the substantia nigra, locus coeruleus, hypothalamus, basal nucleus of Meynert, and neocortex. There is decreased dopamine in the basal ganglia and a loss of choline acetyltransferase (and thus, acetylcholine) in the basal nucleus of Meynert.[5] Many of these patients display extrapyramidal signs without the classic presentation of Parkinson disease.[9] The role of α-synuclein is a common biologic theme in both DLB and PDD, with α-synuclein aggregates found in Lewy bodies and neurites.

Clinical Presentation

CASE 108-2

QUESTION 1: N.G. is a 78-year-old female who was diagnosed with mild NCD 4 months ago. She had been increasingly forgetful and confused from about 1 year before the diagnosis. Approximately 2 months ago, N.G.'s eldest daughter moved into her house to make sure she wasn't alone. N.G.'s daughter noticed that all of the kitchen drawers were partially open, and all of the appliances were unplugged. N.G. told her that she leaves the drawers open just in case she needs to find a knife to protect herself from the "shadow men" at night. A few weeks after N.G.'s daughter moved in, she notes that her mother has fallen

out of bed twice in the middle of the night without major injury and states that her mother "has good and bad days."

At the physician visit, N.G. was found to be medically stable. Vital signs, serum chemistries, and complete blood cell count were within normal limits. Her MMSE score was 22/30. During the review of systems, N.G.'s eldest daughter had to answer some questions because N.G. appeared either not to hear them or to ignore them. On physical examination, she demonstrated mild cog-wheeling rigidity bilaterally, bradykinesia, and masked facies; she did not display a resting tremor.

What is the most likely explanation for N.G.'s presentation?

Given her physical health, inability to live alone because of impaired cognition, and MMSE score, N.G. meets the criteria for dementia. Her rigidity, bradykinesia, and masked facies are consistent with early Parkinson disease (see Chapter 59, Parkinson Disease and Other Movement Disorders). There have been revised criteria for the clinical diagnosis of DLB (see Table 108-1).[74] N.G. exhibits all the central features, two core features, and the supportive features of repeated falls and REM sleep behavior disorder. Her presentation is consistent with probable DLB versus PDD because of her temporal sequence and lack of well-established diagnosis of Parkinson disease.

Treatment

Case 108-2, Question 2: What is an appropriate treatment for N.G.?

To date, ChEIs are the only treatment strategy for the cognitive symptoms of both PDD and DLB. All ChEIs have demonstrated symptomatic benefit in patients with DLB.[75,76] The largest randomized, placebo-controlled trials have used rivastigmine (up to 12 mg/day) in subjects with mild-to-moderate disease, and this medication has received FDA indication for PDD. Rivastigmine was reported to worsen tremor in 10% of the patients with PDD; yet, overall, there was not a statistically significant difference between groups.[72] Rivastigmine treatment has demonstrated improvements in

apathy, anxiety, delusions, and hallucinations when titrated appropriately to doses of 6 to 12 mg daily.[77] Dose initiation, titration, and monitoring are conducted in the same manner as when ChEIs are used for the treatment of AD.

N.G.'s symptoms of Parkinson disease should be fully evaluated, and appropriate treatment, such as levodopa/carbidopa, should be started (see Chapter 59, Parkinson Disease and Other Movement Disorders). Because several medications for parkinsonism can have psychiatric effects, it is important to monitor for adverse effects such as worsening psychosis and cognition. Typical antipsychotics, such as haloperidol, may worsen her extrapyramidal symptoms (EPSs) and should be avoided. Pimavanserin is the only antipsychotic indicated for Parkinson disease psychosis.[78] Other less costly antipsychotics, namely quetiapine and clozapine, may be less likely to exacerbate the parkinsonism, but efficacy is limited.[72,78]

VASCULAR DEMENTIA

Etiology

Vascular dementia (VaD) is a broad classification of cognitive disorders caused by vascular disease. The most common cause of VaD is occlusion of cerebral blood vessels by a thrombus or embolus, leading to ischemic brain injury.[79,80] In the majority of cases, the dementia syndrome is the result of multiple individual cerebral infarcts, a single infarct in an area related to cognitive function, or diffuse white matter lesions in the subcortex.[12] A number of diseases, including atherosclerosis, arteriosclerosis, and vasculitis, lead to the production of emboli and thrombi that potentially occlude brain vessels. Hemorrhagic phenomena and disorders such as HTN or cardiac disease can produce episodes of cerebral ischemia or hypoxia and are responsible for some cases of VaD.[79–81] Specific risk factors for VaDs include advancing age,

diabetes mellitus, small vessel cerebrovascular disease, HTN, heart disease, hyperlipidemia, tobacco use, and alcohol use.[80–82]

Neuropathology

VaDs are typically subcortical. Most patients with VaD have blockage of multiple blood vessels and infarction of the cerebral tissue supplied by those vessels.[81,82] When the distribution of a large artery or medium-size arteriole is blocked, focal neurologic deficits can result (see Chapter 61, Acute Ischemic and Hemorrhagic Stroke). Depending on the area affected, there may be significant cognitive impairment. More often, however, a patient may have experienced transient ischemic attacks (TIAs) or multiple microinfarcts that have remained unrecognized.[81,82] Patients with subcortical VaDs often exhibit small, deep ischemic infarcts in arterioles of the basal ganglia, thalamus, and internal capsule.[81,82] A history of atherosclerosis, diabetes mellitus, or HTN is often present without a history of stroke.[81,82] MRI scans can be very useful in diagnosing VaDs because areas of cerebral infarction are easier to visualize than they are with CT scanning (**Fig. 108-3**).[17,83] Lesions in white matter may occur in as many as 85% of patients with VaD. Deep white matter lesions known as leukoaraiosis often include demyelination and may represent early changes in dementia.[81] Because of the etiologic factors involved, VaD typically has an earlier onset than AD and affects more males than females.

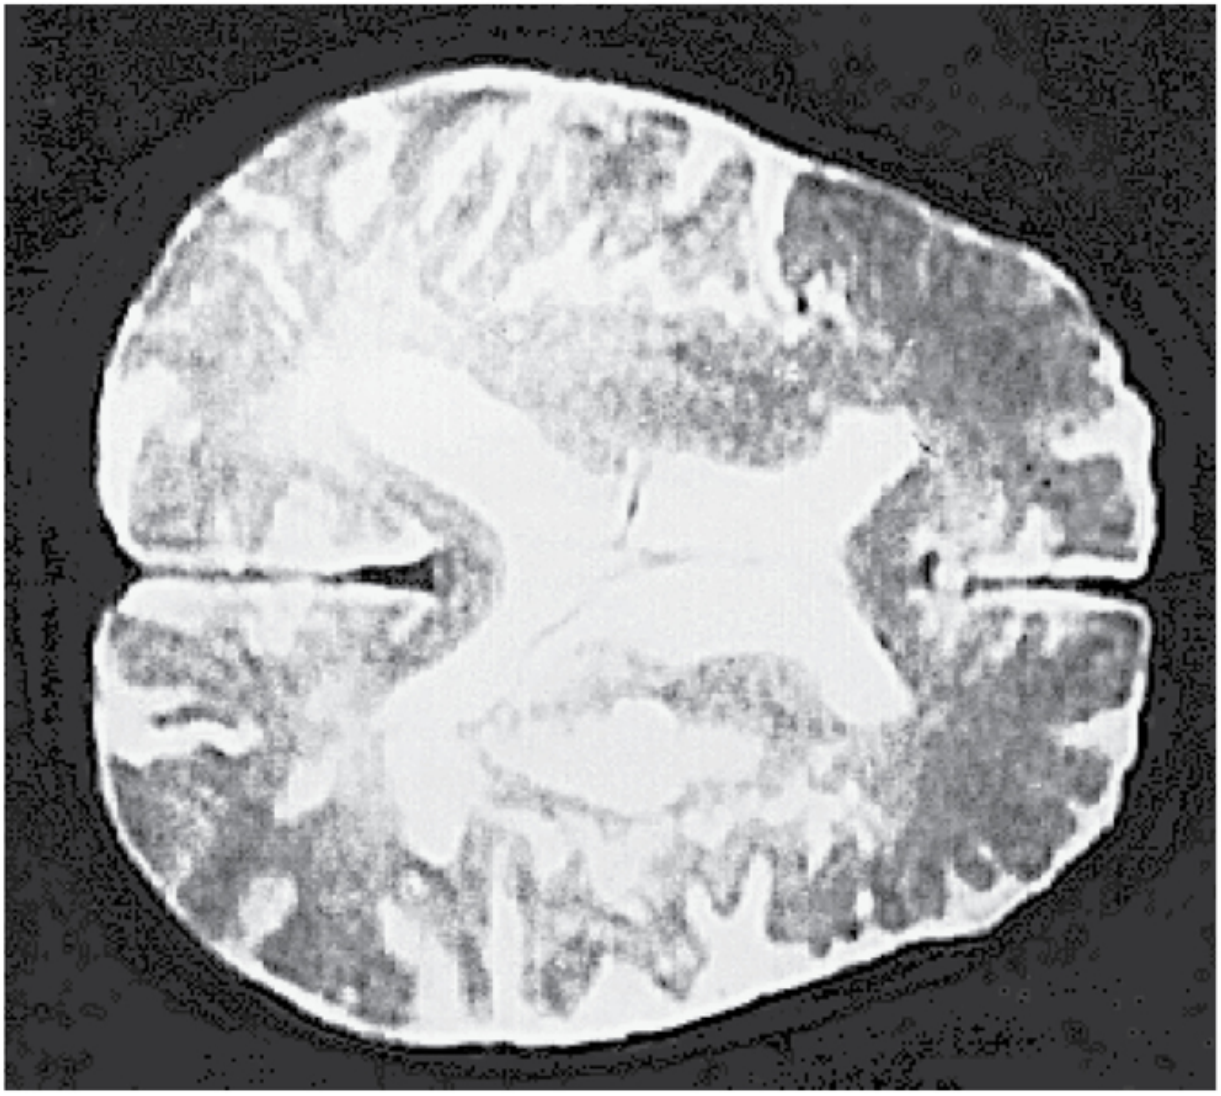

Figure 108-3 A large stroke is visible to the right of the ventricles. There is evidence of atrophy in the right temporal area.

Clinical Presentation

CASE 108-3

QUESTION 1: F.S., a 74-year-old male, is accompanied by his grandson because he is concerned that F.S. is "depressed." F.S.'s grandson reports that F.S.'s daily routine consists of eating breakfast, watching television for several hours until dinner, then sitting on the porch until bedtime. F.S. has difficulty recalling recent news despite watching the television for most of the day; he reports that the news is not "exciting enough" to remember it. The memory loss

has been slowly progressive and started ~1 to 2 years ago. F.S.'s grandson reports that he started to complete F.S.'s tax returns this past year because "it took F.S. too long." F.S. also now relies on his grandson for transportation and requires reminders for his medical appointments. He has a past medical history significant for HTN for 20 years (currently prescribed carvedilol 25 mg twice daily) and hyperlipidemia (currently prescribed atorvastatin 40 mg). He also has a history of nicotine use with a 25-pack-year history; however, he stopped smoking cigarettes 1.5 years ago after his triple coronary artery bypass graft procedure. His family history is positive for hyperlipidemia and heart disease.

On physical examination, F.S. is found to be a mildly obese male who is well dressed and groomed, alert, and oriented to person. His BP is 160/92 mm Hg sitting and 168/95 mm Hg standing. Cardiac examination is normal. Neurologic findings include somewhat diminished extraocular movements laterally and slightly asymmetric reflexes, with right greater than left. Muscle tone is normal in the lower extremities. Vibratory sensation is diminished but within normal limits for his age. His score on the MoCA was 22/30, including errors in orientation and recall. Psychologic evaluation found him to be mildly depressed.

A full laboratory analysis was generally within normal limits. F.S.'s serum potassium (3.5 mEq/dL) and sodium (137 mEq/dL) were in the low normal range, and his blood urea nitrogen (22 mg/dL) was in the upper normal range. Serum low-density lipoprotein (LDL) was 110 mg/dL, and fasting triglycerides were 230 mg/dL. A chest radiograph revealed a moderately enlarged heart; his electrocardiogram was normal. A transthoracic electrocardiogram visualized left ventricular hypokinesis with an estimated left ventricular ejection fraction of 50%. An MRI scan of the brain indicated generalized atrophy with enlarged ventricles, periventricular white matter ischemic changes, and small cortical infarcts in the right parietal lobe.

What subjective and objective evidence exists for a diagnosis of dementia in F.S.?

F.S.'s major reported problem is "depression" and impaired memory that he attributes to disinterest. However, his family began to note memory problems a full year before that episode, with progression over time. Although F.S. denies that his impairment significantly affects his daily routine, he has stopped driving and relies on his grandson for assistance with financial matters. His memory difficulties appear to have affected his mood and made him feel useless. These factors satisfy the *DSM-V* criteria for interference with normal activities.[1]

F.S.'s inability to drive reflects poor judgment behind the wheel of a car; a disturbance of higher cortical function is indicated by his

need for assistance with financial matters. There is no evidence of delirium being present. Evidence of an organic cause is provided by the MRI scan.

Diagnosis

Case 108-3, Question 2: What type of dementia does F.S. have?

There is sufficient evidence to indicate that F.S. suffers from an NCD. DSM-V provides diagnostic criteria for VaD (see Table 108-1), and it appears that the history and findings satisfy the possible VaD (unclear of temporal relationship between coronary artery bypass graft and decline).[1,79] VaDs commonly present suddenly after a cerebrovascular insult. This is followed by a period of stability and further declines after additional episodes, often in a stepwise pattern. Cognitive impairments are variable and depend on the area of the brain affected by the insult.[1,12]

With the exception of the coronary artery bypass graft, F.S.'s deterioration has had a pattern that resembles a downhill slide rather than a stepwise decline. Although his cognitive deficits are "patchy" (eg, he appears to have no language difficulty), they are not particularly prominent. F.S. displays some neurologic signs and symptoms, including diminished extraocular movements, and asymmetric reflexes, but they are subtle and might be easily missed by an untrained observer as being related to dementia. Reliance solely on the clear presence of diagnostic criteria may often lead to a missed diagnosis.[83] It is important to differentiate dementia and depression, as they both can present with memory loss and poor attention. Neurocognitive tests, such as the Geriatric Depression Scale or Patient Health Questionnaire-9 (PHQ-9), can be used to identify the presence of depression.[84,85] The Hachinski Ischemic Scale ranks signs and symptoms associated with cognitive impairment of cerebrovascular origin and is used to help differentiate between AD and VaD.[81] According to this scale, F.S.'s depression,

HTN history, and focal neurologic signs and symptoms are sufficient to indicate VaD.

F.S.'s history and clinical presentation do not suggest dementia caused by a single large stroke or several small strokes. Large strokes produce significant motor damage, typically on one side of the body (the side contralateral to the stroke). Multiple smaller strokes cause prominent motor deficits in discrete areas controlled by the affected areas. Neither of these patterns describes F.S.'s condition. However, he is clearly exhibiting signs of dementia and has significant cerebrovascular disease. He possesses several risk factors for a VaD, including HTN, smoking, hyperlipidemia, and coronary artery disease. His MRI indicates a lacunar stroke with multiple small infarcts in the deep penetrating arterioles at the base of the brain, particularly in the internal capsule, thalamus, and pons (see Chapter 61, Acute Ischemic and Hemorrhagic Stroke). These MRI findings are consistent with F.S.'s long-standing HTN and neurologic presentation.

Treatment

Case 108-3, Question 3: How should F.S. be managed?

Several treatment options that modify risk factors for VaDs are available.

SMOKING CESSATION

F.S. has taken appropriate action to stop smoking tobacco because cigarette smoking reduces cerebral blood flow and increases the risk for stroke. Among smokers with VaD, cessation of cigarette use improves cognitive performance.[86]

ANTIHYPERTENSIVE THERAPY

HTN and hyperlipidemia, both present in F.S., are additional risk factors for stroke and VaD. Control of systolic HTN reduces the risk

of stroke by 36% in older adults,[87] and maintaining the systolic BP between 135 and 150 mm Hg is associated with improved cognition among patients. The lower boundary of systolic BP that may lead to inadequate cerebral perfusion and resultant cognitive impairment is unclear; however, maintaining the systolic BP >120 mm Hg did not demonstrate a negative effect on cognition in certain patient populations.[88] For individuals without dementia, nonpharmacologic treatment (eg diet, weight loss, exercise) is an essential component. The antihypertensive agent must be chosen carefully in this population to maximize adherence and minimize adverse reactions.[89],[90] Both thiazide diuretics and β-adrenergic blockers may increase lipid levels, a potential complication in F.S. α-Adrenergic blockers and sympatholytic agents may cause depression, negative cardiac outcomes,[91] or impair cognitive activity. Calcium channel blockers or angiotensin-converting enzyme inhibitors are acceptable because they are well tolerated by older adults and may help preserve renal function in patients with diabetes mellitus (see Chapter 9, Essential Hypertension).

Dihydropyridine calcium channel blockers have been shown to improve cognition in patients with dementia and may reduce the risk of dementia in older adults with isolated systolic HTN.[92] Because F.S. has coronary artery disease, he may benefit from the use of a calcium channel blocker, such as amlodipine 5 mg daily or nifedipine XL 60 mg once daily (see Chapter 12, Chronic Stable Angina). An alternative medication may be candesartan 8 mg once daily, as when compared to an angiotensin-converting enzyme inhibitor (lisinopril), patients prescribed candesartan had higher performance on executive function and delayed recall/learning neuropsychiatric tests after one year of therapy.[93] Both agents exhibit the advantage of once-daily dosing over some other agents within their respective classes. This feature is important for maximizing adherence in patients with declining memory.

ANTILIPEMIC THERAPY

Similar to systolic BP control, control of hyperlipidemia decreases the risk of stroke by at least 16% in older adults.[94] The mainstay of cholesterol-lowering treatment is statin therapy, given their proven cardiovascular and cerebrovascular event prevention effects (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). High-intensity statin therapy is recommended in adults 75 years of age or younger; however, in F.S.'s case, moderate-intensity statin therapy can also be considered given a potential higher risk for adverse events.[95] Generally, statin therapy should not be expected to worsen cognitive impairment. However, it is theorized that hydrophobic stations (eg, simvastatin, atorvastatin, lovastatin) have higher central nervous system penetration and a higher risk for affecting cognition. Thus, more hydrophilic statins (eg, pravastatin, rosuvastatin) may be preferred in older adults with cognitive impairment.[96] Furthermore, simvastatin 80 mg/day should be avoided in all adults because of the increased risk for statin-associated muscle symptoms and rhabdomyolysis. An appropriate alternative statin therapy for J.S. could be rosuvastatin 20 mg daily or atorvastatin 40 mg daily, both of which are high-intensive statin therapies and are dose-equivalent to simvastatin 80 mg daily. Rosuvastatin may be preferred given its hydrophilicity and theoretical lower risk to affect cognition.

Generally, lifestyle modifications, such as weight loss and diet, are first-line treatments for hypertriglyceridemia. In adults ages 75 years and younger with fasting triglycerides >499 mg/dL, statin therapy is recommended.[95] Eicosapentaenoic acid (eg, icosapent ethyl) in addition to statin therapy may provide additional cerebrovascular benefits in older adults with statin-resistant hypertriglyceridemia and high or very high risk for clinical atherosclerotic cardiovascular disease; however, further trials are needed to reproduce this effect in a more diverse population.[97],[98] Thus, weight loss and diet modification, in addition to switching his statin to high-intensity, would be recommended for F.S. at this time for his hypertriglyceridemia.

ANTIPLATELET THERAPY

Prophylaxis against future cerebrovascular events is indicated in VaD; but few studies that have specifically focused on individuals with dementia are available. Cerebral perfusion and cognitive performance were improved in patients with VaD receiving aspirin 325 mg/day for 1 year when compared with a control population.[99] Guidelines from the American Heart Association and the American Stroke Association recommend the use of antiplatelet therapy in patients with a history of TIA or atherothrombotic stroke that is not of cardiogenic origin. Aspirin in doses of 50 to 325 mg/day, clopidogrel 75 mg daily, or ticagrelor 90 mg twice daily (with or without cilostazol 200 mg daily) are all effective treatments for stroke prophylaxis.[100] Direct-acting oral anticoagulants (DOACs) or warfarin are recommended after cardioembolic cerebral ischemic events.[100],[101] However, only aspirin has been studied specifically in patients with VaD. Cerebrovascular benefits usually outweigh bleeding risk (ie, GI bleeding) when aspirin is being used for secondary prevention of cerebrovascular events; however, bleeding risk should be carefully evaluated when being used for primary prevention[102] or in high-risk patients (eg, those with hemorrhagic cerebrovascular accident [CVA], cerebral angiopathy, advanced age). Given F.S.'s low bleeding risk, aspirin 81 to 325 mg daily is an appropriate first choice.

CHOLINESTERASE INHIBITORS

Deficits in cholinergic transmission and nicotinic receptor binding abnormalities have been noted in VaD.[103] Clinical trials with donepezil,[104] galantamine,[105] and rivastigmine[106] have demonstrated improvement in cognition and daily function among patients with VaD. As of yet, however, the use of these agents remains investigational and controversial. Because the use of these agents is not FDA approved for VaD, F.S. and his family should have a thorough discussion with his physician regarding the potential risks and benefits when considering ChEI treatment for him.

MANAGING FUNCTION

F.S. should be referred for physical and occupational therapy for an assessment of his strength, gait, and daily function. Physical therapy can help him maintain his strength. Occupational therapy can provide him with equipment and strategies to adapt to his dizziness and avoid falls. In addition, the use of reminder notes and labels around the house will assist him in maintaining his independence.

BEHAVIORAL DISTURBANCES IN DEMENTIA

Several types of behavioral disturbances may develop during the course of a dementia and occur in almost all patients, particularly during the later stages (**Table 108-6**).[17,107] Behavior symptoms include a wide range of disturbances, including agitation, apathy, wandering, verbal and physical aggression, and psychotic symptoms.[107,108] Agitation in dementia has been described as an excessive motor activity with a feeling of inner tension that may lead to related symptoms such as anxiety, irritability, motor restlessness, and abnormal vocalization.[17] Sleep disorders and mood disorders, such as anxiety and depression, also are common.[109] Agitation and anxiety are often managed best with nonpharmacologic treatment. Pharmacologic interventions are appropriate when nondrug therapies are unsuccessful and/or the behavior is severe or harmful to the self or others. Nonpsychologic behaviors such as wandering and inappropriate motor activity respond better to environmental modification than to drug therapy.[107,108] The first step in evaluating altered behavior in patients with dementia is to ensure that the problem is not the result of an unrecognized medical problem (eg pain, infection, psychiatric cause, constipation), environmental factors, or caused by an adverse effect of a medication (see Chapter 107, Geriatric Drug Use).

Table 108-6
Behavior Disturbances in Dementia

Behavior	Typical Presentation	Nonpharmacologic Treatment	Pharmacologic Treatment
General strategies		Safety-proof living areas Issue one-step commands for directions Maintain a daily routine of activities Avoid arguing incorrect statements Avoid startling the patient Limit unusual or overly stimulating environments	
Anxiety	Excessive worrying, sleep disturbances, rumination	Listen to, and acknowledge frustrations Redirection Exercise Engage in enjoyable activities Sleep hygiene practices Limit noise and distractions	Trazodone Buspirone (if no insomnia) Short-acting benzodiazepine SSRI antidepressant
Depression	Withdrawal, loss of appetite, irritability, restlessness, sleep disturbances	Exercise Engage in meaningful activities	Trazodone SSRI antidepressant
General agitation and restlessness	Repeated questions, wandering, pacing	Distraction and redirection Break down tasks into simple steps Provide enclosed area for exercise	Often unresponsive to medications
Paranoid behaviors	Delusions (often of theft), hallucinations, misperceptions	Reassurance Distraction, rather than confrontation Remove potential sources of confusion (eg, mirrors and other reflective surfaces)	Atypical antipsychotic, if not responsive to other strategies and person is harmful to self or others SSRI antidepressant, if associated with withdrawal, tearfulness, themes of loss
Aggressive behaviors	Physical or verbal aggressiveness toward others, excessive yelling and screaming, manic features	Identify the precipitating cause or situation Focus on the patient's feelings and concerns Avoid getting angry or upset Maintain a simple, pleasant, and familiar environment Use music, exercise, etc., as a calming activity Shift the focus to another activity	Anticonvulsant, such as divalproex or carbamazepine, possibly in combination with an atypical antipsychotic when other strategies do not work

SSRI, selective serotonin reuptake inhibitors.

Agitated Behaviors

CASE 108-4

QUESTION 1: B.L., a 54-year-old male, has recently been diagnosed with early-onset AD, for which he is prescribed rivastigmine 13.3 mg/day patch once daily. His past medical history is also significant for benign prostatic hyperplasia (BPH), for which he is prescribed doxazosin 4 mg at bedtime. He has given up on driving because of an episode of forgetting how to get home and, instead, relies on his college-age son. He also expresses worry about the burden he will place on his family as his condition worsens. At times, B.L. gets frustrated that he has to rely on his wife to assume responsibility for paying the monthly bills. B.L.'s wife notes that he follows her around the house and paces in circles when he gets impatient. Recently, he has had episodes of dizziness when he wakes up in the morning, which he feels like he could fall.

How should B.L.'s agitation and anxiety be managed?

Anxiety and unfocused activity are common problems in the early stages of dementia. Agitation is a general term that, although commonly used, is subject to wide interpretation. It typically is used to describe specific behaviors such as restlessness, irritability, or unfocused motor activities. Patients are aware of their progressive cognitive decline and have sufficient insight to understand the consequences. B.L.'s frustration related to his inability to perform tasks indicate insecurity and anxiety; pacing through the house is an example of restlessness and unfocused behavior. B.L. is exhibiting anxiety, as evidenced by his worry about placing a burden on his family. His poor sleep is attributable to both nocturia and anxiety.

If B.L.'s behavior represents a sudden or rapid change, his physician should first evaluate him for a medical condition such as infection, pain, or a medication-related problem. Although B.L. has previously been taking doxazosin without difficulty, he may be experiencing autonomic dysfunction that can increase his risk for falls. Doxazosin should be switched to an α-2-selective blocker; if his nocturia increases, a 5-α reductase inhibitor may be considered (see Chapter 109, Geriatric Urologic Disorders). This change may help with his orthostasis, nocturia, and disturbed sleep.

Case 108-4, Question 2: B.L.'s mental status continues to decline to the point that he requires help with grooming and dressing. During a physician visit, he accuses his wife and son of stealing from him. He also cannot locate his coin collection, which he placed in a "safe" location when his memory began to decline; during the night, he rummages through the house looking for it. He believes his family has been plotting to steal his assets and then turn him out onto the street. B.L.'s son reports that B.L. has been verbally abusive and has threatened several members of the family recently. How should B.L.'s paranoid behavior be managed?

Once medical problems have been ruled out or corrected, he should be evaluated using a systematic approach, as behavior problems are part of a chain of events. B.L. may be described as "agitated," but his behavior is shadowing his wife and pacing through the house. The behavior has an antecedent; because he has a dementia, he may be unable to initiate a meaningful or enjoyable activity on his own, and consequently he becomes bored. The consequence of his boredom is that he annoys his wife and paces the house. This evaluation represents what often is termed an "A-B-C" approach, for *antecedent, behavior, consequence.*[110] Pacing is a demonstration of unfocused energy. B.L.'s wife can give him simple tasks to perform, such as drying dishes, folding laundry, or simple gardening, to help channel his energy. It also may relieve his anxiety and insecurity. She also could accompany him on walks to alleviate his fear of getting lost. She may want to consider enrolling him in an adult day-care program. This would give him meaningful activity that might help him use up his excess energy and sleep better at night. It also will provide her with some respite and avoid or delay caregiver burnout. Appropriate strategies to manage agitated behaviors without medication are listed in Table 108-6.

When nonpharmacologic interventions are not successful in reducing anxiety, irritability, and similar behaviors, medications can be considered. Benzodiazepines are the most commonly used anxiolytics and will address B.L.'s insomnia and anxiety. However, they are associated with several negative outcomes in older adults, including confusion, amnestic syndromes, ataxia, and falls.[111] Benzodiazepines, in addition to other medications, may be

considered potentially inappropriate medications in older adults as described in the 2019 American Geriatrics Society Beers Criteria.[112] If a benzodiazepine is clinically warranted, agent such as lorazepam or oxazepam may be used if necessary, but only for a short term and with caution.[110]

Another potentially avoidable class of drugs include anticonvulsants or mood stabilizers because of their questionable benefit. Carbamazepine may decrease agitation in patients with NCDs; but conflicting data also demonstrate no significant difference compared to placebo.[113] Carbamazepine is also a strong CYP3A4 inducer (caution with ChEIs, trazodone, and some antipsychotics) as well as carries the rare, but serious risk for agranulocytosis and Stevens–Johnson syndrome. Conversely, valproic acid and its derivatives have not been found to be effective for agitation associated with NCD and may also carry a higher risk for harmful effects, such as drowsiness, fatigue, and gait imbalances.[114] These agents should generally be reserved as last-line agents prior to antipsychotic therapy. Given B.L. has not tried antidepressant therapy and has a risk for drug interactions (with rivastigmine and doxazosin), carbamazepine is not appropriate to initiate at this time.

Trazodone is a sedative antidepressant that is effective for insomnia and agitated behaviors in patients with AD.[110],[115] Treatment is started at 25 mg at bedtime and may be increased to a dose of 250 mg/day in divided doses. Another alternative treatment is buspirone, which does not cause the cognitive impairments associated with benzodiazepines. Dosage begins at 5 mg three times daily and may be increased up to 15 mg three times daily. However, buspirone will not concurrently manage B.L.'s insomnia because it has no sedative effect, and there is no reliable evidence that it is efficacious in anxiety associated with dementia.[115] Citalopram has been shown to reduce agitated behaviors in people with dementia and could be used.[116] Emerging evidence suggests that dextromethorphan–quinidine combination may be efficacious in reducing agitation; but caution exists in light of drug–drug interactions as well as limited data.[117]

If the nondrug strategies are ineffective in reducing B.L.'s insomnia and agitation, trazodone should be initiated at a dose of 25 mg at bedtime. It may be increased by 25 mg/day at 5- to 7-day intervals, up to 100 mg. Doses above 100 mg/day should be split into two daily doses.

Psychosis

Delusions and hallucinations are common among individuals with dementia. Paranoid symptoms, often accompanied by aggression, have been reported in more than half of dementia patients.[118] Delusions typically involve suspicion of theft by family members, which may be secondary to the patient's inability to remember where valuable items were placed and incorrectly concluding that they were stolen. Another common delusion is the misidentification of people or objects.[119] Capgras syndrome, the belief that a person has been "replaced" by an identical-looking impostor or the belief that photographs or television pictures are real individuals, may occur in almost half of demented individuals.[118]

There are a few behavioral interventions that could be tried first before resorting to medications, which produce limited benefits and are accompanied by significant risk.[120],[121] The first step is to conduct a person-centered examination of the symptoms. Several questions need to be answered. What is the significance or meaning of these behaviors to B.L.? (For example, he cannot locate items that are valuable to him and does not recall where they are.) What triggers his thoughts and outbursts? (He may assume the items were stolen and believes that his family, knowing their location, has taken them for their own gain.) How is the family's response further angering him? (If the family searches for and finds the items, it may reinforce his delusion that they stole them.) The family should be educated that paranoid behavior is common in dementia and that it is likely to pass as the disease progresses. Depending on how fixed the paranoia is, distraction or redirection, such as changing the subject to something more pleasant, or initiating a pleasant activity, could

resolve the problem. Regardless of the strategy, they need to be taught not to argue or debate with B.L. but to share his concern. When these strategies fail, then, depending on severity, it may be necessary to resort to medication.

Paranoid symptoms respond best to antipsychotic agents, although these are not highly effective, and no single antipsychotic is more effective than any other. Delusions, hallucinations, aggression, and uncooperativeness symptoms respond best, but overall improvement occurs in only a minority of patients.[115],[122] The CATIE-AD trial compared olanzapine, quetiapine, risperidone, and placebo for the treatment of psychosis, aggression, and agitation for up to 36 weeks in patients with AD. Improvement was noted in 32%, 26%, 29%, and 21%, respectively. The authors concluded that efficacy of the agents was offset by adverse effects.[122] There are no antipsychotic medications that are approved by the FDA for use in the management of behavioral symptoms in people with dementia. Recently, pimavanserin, a serotonin 2A receptor antagonist and inverse agonist, was FDA approved for Parkinson disease psychosis. In clinical trials, it was associated with a modest reduction in the frequency of hallucinations and delusions in patients with Parkinson disease psychosis.[123] Black box warnings are present for all agents, including pimavanserin, because of the increased risk for stroke and mortality when used in this population.[120],[121],[124],[125] Consequently, any use of antipsychotics in a person with dementia is for an unapproved use and requires a full discussion between the physician, patient, and caregivers.

The risks and potential benefits of therapy must be carefully weighed for B.L. before determining the appropriate treatment. The choice of an antipsychotic agent is determined by the symptoms displayed by the patient as well as the potential for adverse effects. B.L. is experiencing a delusion of theft, suspiciousness, and aggressive behavior. It is possible that the verbal abuse and threats are consequences of fear brought on by the false belief that his family is stealing from him and plans to abandon him.

B.L. has no major contraindications to the use of any antipsychotic agent, and his target symptoms will probably respond to any of the

available agents. Therefore, a therapeutic trial is appropriate as supported by the American Psychiatric Association guidelines.[126] The choice can be made according to which antipsychotic agent is least likely to cause intolerable adverse effects. Risperidone has been evaluated in a case series and in a large double-blind, placebo-controlled trial.[127],[128] In the case study series, symptoms improved in half of the patients taking dosages ranging from 0.5 mg every other day to 3 mg twice daily. However, 50% also experienced EPS, even at the lowest dosage used.[127] Subjects in the double-blind trial received either placebo or risperidone at dosages of 0.5 mg/day, 1 mg/day, or 2 mg/day for 12 weeks. Daily doses of 1 or 2 mg reduced psychosis and improved behavior, but EPS and somnolence were common adverse effects.[128] Low doses of olanzapine, 5 to 15 mg/day, were superior to placebo for reducing agitation, aggression, and psychosis during a 6-week study among nursing facility residents.[129] Somnolence and gait disturbances were the most common adverse effects. Quetiapine has been shown to reduce agitated and psychotic behaviors at doses of 100 to 200 mg/day.[130] Clozapine poses a significant risk for hematologic toxicity and requires careful monitoring. Because B.L. does not have cardiovascular or cerebrovascular risk factors, but does have gait or balance problems, quetiapine 25 mg at bedtime can be initiated. Quetiapine doses can be increased by 25 mg/day, up to 200 mg/day in divided doses. Once his behavior has stabilized, the medication should be continued for about 4 months. At that time, the dose should be decreased in weekly intervals to determine whether the medication is still required. B.L. should be monitored closely for adverse effects, including EPS, which can occur with the atypical antipsychotics.[126],[127],[131]

Aggressive Behaviors

Case 108-4, Question 3: After 3 months, B.L.'s delusions have subsided, but he continues to be verbally abusive and often displays angry, emotional outbursts, especially when he requires help with bathing or toileting. At other

times, he is withdrawn and apathetic. He has also been found wandering in the neighborhood on three occasions. These behaviors persist despite treatment with quetiapine 100 mg twice daily. What alternative treatments can be attempted?

Although psychotic symptoms respond to antipsychotic agents, many other behaviors do not. Up to 90% of patients with dementia exhibit at least one disruptive behavior, such as angry outbursts, screaming, and abusive language, and many display multiple aggressive behaviors.[132] As many as 32% exhibit moderate-to-severe behaviors.[132] Such behaviors are typically directed at caregivers, precipitated by receipt of assistance with ADLs, such as bathing and toileting, and increase in frequency with dementia severity.[110],[131] Several of these behaviors may be merely defensive responses to perceived threats in cognitively impaired individuals.[131] Behavioral disturbances must be addressed because they can have a negative effect on the patient's ability to perform ADLs.[110]

Some behaviors exhibited by B.L. are not likely to respond to medications. Wandering is typically unaltered by the use of medications unless the patient is oversedated. Nonpharmacologic treatments, such as periods of physical exercise and rest, or environmental modification is much more effective.[108],[110],[132] B.L.'s reactions to assistance with bathing and toileting may be caused by confusion and fear. Breaking the tasks down to step-by-step procedures, accomplished individually, often helps modify aggressive behaviors.[38]

Verbal abuse and aggressiveness place both the patient and the caregiver at risk for injury and may lead to abuse. In these situations, the patient and the caregiver may each be a precipitator or a target of abuse.[131] In some small studies, anticonvulsant agents have been shown to reduce rage and aggressive behaviors in patients resistant to treatment with antipsychotics. Carbamazepine and valproic acid (including divalproex) are the most well-studied agents.[133],[134] Although initial trials were promising, later studies did not establish efficacy. The lack of benefit plus concerns about toxicities with each agent have led to recommendations that these agents not be

used.[113],[114] The addition of an antidepressant medication may be helpful, as described below. Wandering typically does not respond to pharmacologic intervention. Appropriate strategies include environmental modification, such as placing child-safety locks on exit doors; providing activities and other distractions; and having a safety plan, such as the Safe Return program. As described for his paranoid behavior, a person-centered evaluation using the A-B-C approach should be conducted to determine the cause and effects of his aggressiveness. If B.L.'s aggressive behaviors continue, his family may need to consider obtaining in-home assistance or placement in an assisted-living facility designed for the care of patients with dementia.

Depression

Case 108-4, Question 4: How should B.L.'s social withdrawal and apathy be treated?

Depression often accompanies dementia and may significantly impair a patient's functional capacity, cognitive abilities, and communication.[1],[135] B.L. is withdrawn and apathetic, symptoms suggestive of depression. Screaming and irritability may be considered symptoms of depression in individuals with dementia, perhaps reflecting feelings of loneliness, boredom, or the need for attention.[136] Because a definite diagnosis of depression relies heavily on a patient interview and response to questions, a formal diagnosis in patients with dementia is difficult. Therefore, patient observation is an important component for making a clinical evaluation. It is possible that he is reacting to a sense of loss of not only his memory and function but also a loss of self. He also may feel isolated by the inability to communicate with others or participate in the outside world. Helping him to engage in meaningful activities and social engagement, perhaps as simple as going on a walk or attending adult day care, may help alleviate his apathy and reverse his

withdrawal. Such a strategy is appropriate to try before considering an antidepressant.

The selective serotonin reuptake inhibitors have not been well studied in patients with dementia but are effective antidepressants with adverse effects that are better tolerated than those of the tricyclic antidepressants. Sertraline, in doses of 50 to 150 mg/day, was superior to placebo in reducing depression in AD patients during a 12-week trial.[137] Citalopram has also demonstrated effectiveness; in contrast, fluoxetine and fluvoxamine have not demonstrated benefit.[113],[116] Either sertraline 50 mg daily or citalopram 10 mg daily are reasonable choices to treat B.L.'s symptoms of depression if he does not respond to nonpharmacologic strategies. He should be reassessed in 4 to 6 weeks; if he has not responded, the dose may be increased. Dosages may be increased weekly up to a maximum of 150 mg/day or 20 mg/day, respectively. A full therapeutic trial requires a minimum of 3 months.

Social Support

Case 108-4, Question 5: B.L.'s family indicates that caring for him at home has become so burdensome that they are considering placing him in an institution. What social support services are available to families facing this decision?

Institutionalization is a typical outcome for patients in the late stages of dementia. The total care required to manage a patient with dementia usually becomes unmanageable for most families as the disease progresses. Caregiver stress is often exacerbated by the patient's declining memory, inability to communicate, physical decline, and incontinence as well as the caregiver's loss of freedom and depression. Caregivers commonly experience anger, helplessness, guilt, and worry, and suffer from physical stressors such as fatigue and illness.[38]

Outside assistance is essential to families caring for a patient with dementia. Families should be referred to the Alzheimer's Association

as soon as a diagnosis of dementia is received. The association has local affiliates in most major cities. The book *The 36-Hour Day* is a valuable resource for families as well.[138] It describes the symptoms, behaviors, and problems that can be encountered when caring for a patient with dementia.

Support groups, individual and family counseling, and other sources of support are useful and may help families cope for a longer period. However, the key intervention to reduce caregiver stress is respite care, which allows a family time away from the responsibilities of taking care of a frail individual. Respite care brings a person into the home or allows the patient to go to a day-care center or similar environment on a regular schedule. Such programs may delay the need to institutionalize a patient.[38,107,138]

Geriatric Urologic Disorders

Jaini Patel

CORE PRINCIPLES		CHAPTER CASES
URINARY INCONTINENCE		
1	Urinary incontinence is a common condition in older adults and can be classified as acute or persistent. Persistent incontinence can further be classified as urge, stress, overflow, or functional.	**Case 109-1 (Questions 1, 2)**
2	Urge incontinence is managed with nonpharmacologic interventions, such as a toileting schedule, and the use of anticholinergic and β_3-agonist agents.	**Case 109-1 (Questions 3, 4)**
3	Stress incontinence is managed with local estrogens, tricyclic antidepressants, and duloxetine.	**Case 109-2 (Questions 1, 2)**
BENIGN PROSTATIC HYPERPLASIA		

1	Benign prostatic hyperplasia (BPH) is the most common urologic condition in aging males. A wide range of signs and symptoms occurs in BPH that cause patients to seek care.	**Case 109-3 (Questions 1–3)**
2	Management of BPH includes the use of α_{1A}-adrenergic receptor antagonists and 5α-reductase inhibitors, either alone or in combination. Nonpharmacologic treatment and surgery may also be considered for some patients. In general, the use of over-the-counter medications should not be used to treat symptomatic BPH.	**Case 109-3 (Questions 4–7)**

ERECTILE DYSFUNCTION

1	Erectile dysfunction (ED) is a condition that can be a result of neurogenic, hormonal, or vascular disorders. It is therefore essential that a complete urologic workup is conducted to assess the underlying pathophysiology. Underlying conditions should be addressed and treated before symptomatic therapy is initiated.	**Case 109-4 (Questions 1–6)**
2	Treatment for ED consists of a variety of pharmacologic agents, which include phosphodiesterase inhibitors, intracavernous injections, and alprostadil.	**Case 109-4 (Questions 7–14)**

INTRODUCTION

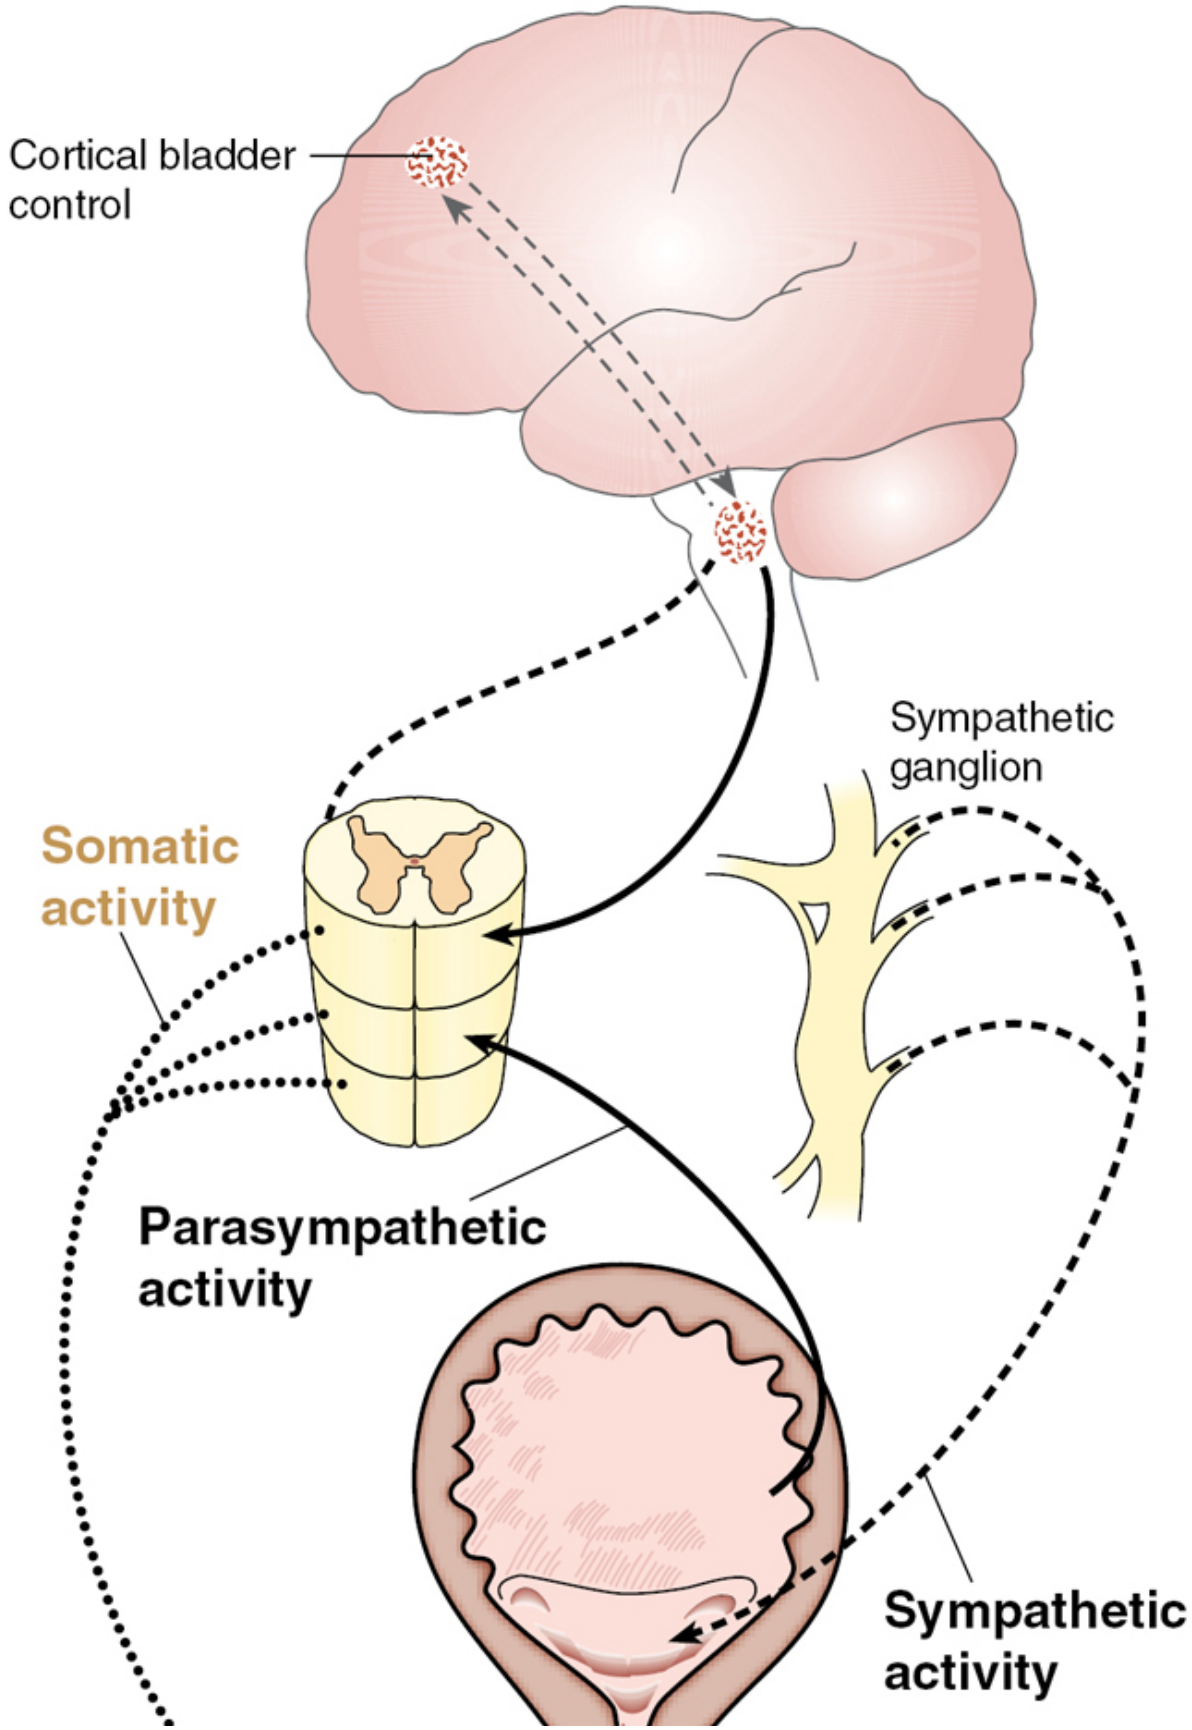
Urinary Incontinence

Urinary incontinence (UI) is defined by the International Continence Society as the involuntary leakage of urine. UI affects ~50% of females between ages 40 and 60 years and an estimated 75% of females ages 75 years or older.[1–3] UI remains one of the most underreported problems despite many negative implications, most likely due to a lack of acceptable ways to discuss voiding-related issues and patients accepting it as a normal part of aging. UI is associated with reduced quality of life from associated conditions such as depression and social isolation, impaired sexual dysfunction, and increased morbidity from complications such as pressure sores and infections.[4]

Anatomy and Normal Physiology

Neuroanatomy and neurophysiology of the bladder and urethra are important to understand the normal physiology of the voiding process. Similarly, identifying the underlying pathophysiology of UI and the subtypes of UI is essential to selecting appropriate treatment modalities. The bladder is like a “pear-shaped balloon” composed of a muscular layer, the detrusor muscle, with a narrow outlet. The detrusor and the bladder outlet functions are coordinated neurologically to allow for storage and expulsion of urine through activation of muscarinic receptors.[5] Out of the five types of muscarinic receptors, the M_3 receptor is primarily responsible for the contraction and relaxation of the detrusor muscle. The detrusor muscle is innervated by the parasympathetic nervous system, and the bladder outlet is innervated by the sympathetic nervous system (α-adrenergic) (**Fig. 109-1**). The proximal smooth muscle (internal) sphincter in the bladder neck also is innervated through the sympathetic nervous system (α-adrenergic). The distal striated

muscle (external) sphincter of the urethra is supplied by the somatic nervous system.



Cortical bladder control
Sympathetic ganglion

Parasympathetic activity
Sympathetic activity

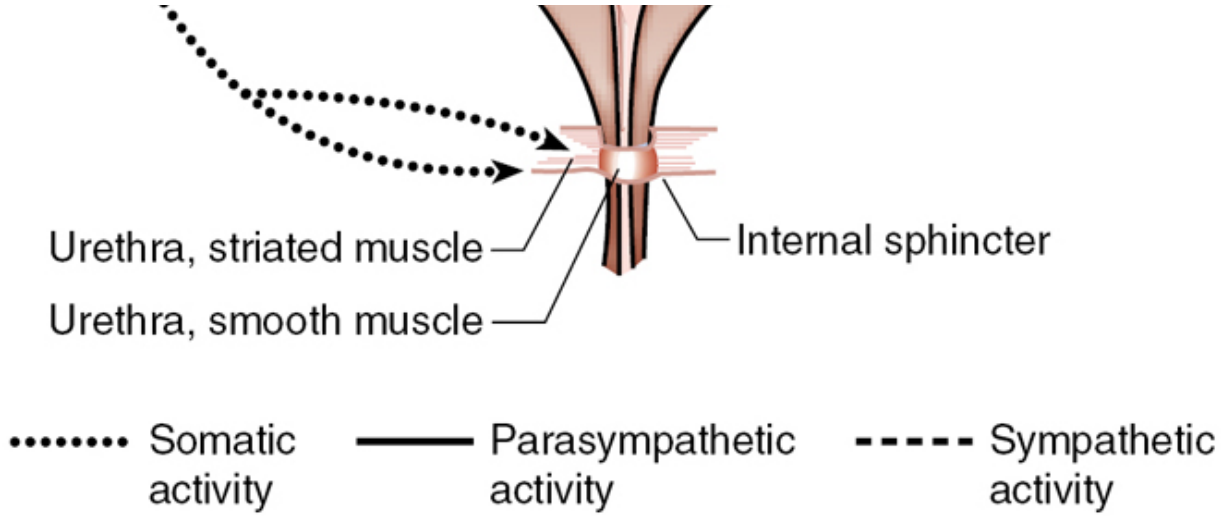

Figure 109-1 Neurologic bladder control.

Urine storage is the result of detrusor muscle relaxation and closure of both the internal and external sphincters. Detrusor relaxation is accomplished by central nervous system (CNS) inhibition of the parasympathetic tone; sphincter closure is mediated by a reflex increase in α-adrenergic and somatic activity. Voiding occurs when detrusor contraction is coordinated with sphincter relaxation. Detrusor contraction is mediated by the parasympathetic nervous system, and relaxation requires inhibition of somatic and sympathetic nerve impulses to the outlet. The bladder capacity is ~300 mL in older adults and ~400 mL in young adults, whereas normal postvoid residual volume (PVR) is typically <50 mL. PVR is the volume of urine left in the bladder after complete voiding.

AGE-RELATED PHYSIOLOGIC CHANGES

Aging brings a myriad of physiologic and functional changes to all the organ systems, including the genitourinary system (**Table 109-1**). With aging, the bladder loses its elasticity, and the sphincter of the urethra loses its ability to maintain its pressure. These aging-related physiologic changes impacting the functionality of the bladder and voiding process stem from varying etiologies. For females, these changes are correlated with the postmenopausal decline of estrogen production. Estrogen has trophic effects on the epithelium and on

tissues lining and surrounding the urethra, bladder outlet, and vagina. Atrophy of these tissues can result in friability, inflammation, susceptibility to infection, diminished periurethral blood flow, and prolapse of pelvic structures. All these effects can precipitate symptoms of UI.[6] For males, the age-related changes in the prostate gland are responsible for many of the changes in urination.[7] These physiologic changes most commonly lead to abnormalities, resulting in either bladder/urethral overactivity or underactivity, leading to incontinence and associated urinary symptoms.

Table 109-1
Age-Related Changes in Urologic Function

↓ Bladder capacity
↑ Residual urine
↑ Uninhibited bladder contractions
↑ Nocturnal sodium and fluid excretion
↓ Urethral resistance in females
↑ Urethral resistance in males
Weakness of pelvic floor muscles in females

MODIFIABLE EXACERBATING FACTORS

Aside from nonmodifiable factors including age and gender, several modifiable factors may contribute or exacerbate UI symptoms. Such factors can be described with the mnemonic DIPPERS (**Table 109-2**).[8] Pharmaceuticals listed in the DIPPERS mnemonic are important to identify to evaluate their risks and benefits and appropriateness of their continuation if the risks of uncontrolled UI outweigh their benefits. Some common pharmacologic agents in the geriatric population that may contribute to UI symptoms are listed alongside the probable mechanism in **Table 109-3**.[9–12]

Table 109-2
Causes of Incontinence: DIPPERS

D	Delirium

I	Infection
P	Psychological
P	Pharmaceuticals (see Table 109-3)
E	Excess urine output
R	Reduced mobility
S	Stool impaction (and other factors)

Table 109-3
Drugs and Substances That Exacerbate Urinary Incontinence Symptoms

Associated Drugs	Probable Mechanism
α-Adrenergic antagonists (eg, doxazosin)	Relaxes the muscle at the bladder outlet and/or decreases internal sphincter tone
Cholinesterase inhibitors (eg, donepezil)	Increases detrusor tone and contractility
Antidepressants (duloxetine)	Mechanism not clearly defined, but potential to result in detrusor overactivity
Oral or transdermal estrogens	Mechanism not clearly defined, but potential to result in detrusor overactivity
Caffeine	Increases urine production, resulting in urinary urgency and frequency; diuretic-like effects
Alcohol	Increases frequency/urgency of urination, diuretic-like effects
Diuretics (eg, furosemide)	Increases urine production, resulting in urinary urgency and frequency
Muscle relaxants/sedatives (eg, diazepam)	Relaxes the urethra (decrease tone)
ACE inhibitors (eg, lisinopril)	Cough (adverse drug event) and subsequent increased intra-abdominal pressure

Antipsychotics (eg, aripiprazole)	Decreased urethral tone through potential α-antagonism
benzodiazepines, opioids, sedatives (eg, alprazolam, hydrocodone)	Impaired physical functioning and/or cognition and/or sedative adverse effect may decrease the desire to urinate. Relaxes the detrusor and may contribute to urinary retention, constipation, and/or fecal impaction
Antihistamines (eg, loratadine, cetirizine, diphenhydramine)	Relaxes the detrusor and may contribute to urinary retention because of anticholinergic properties
α-Adrenergic agonists (eg, tizanidine) or β-blockers (eg, metoprolol)	Urinary retention and increases internal sphincter tone
β-Adrenergic agonists (eg, mirabegron, vibegron)	Inhibits detrusor function causing urinary retention
Anticholinergics (eg, benzatropine)	May cause constipation; thus, impacted stool may lead to urinary retention and/or decrease contractility of the detrusor muscle
Calcium channel blockers (eg, amlodipine)	Decreases bladder contractility, causing urinary retention and/or potential adverse effect of constipation

ACE, angiotensin-converting enzyme.

CLASSIFICATION

UI can be classified into several different types based on underlying pathophysiology and symptoms. If an initial evaluation of a patient's symptoms and medical history identify any underlying etiology or causes for UI, then it is considered reversible UI. If no reversible factors are contributing to UI, then it is considered chronic or

persistent UI. **Table 109-4** reviews the pathophysiology and symptoms of various UI types: stress urinary incontinence (SUI), urge urinary incontinence (UUI), overflow incontinence (OI), and functional urinary incontinence (FUI). Of note, UUI also contains a subtype class known as overactive bladder (OAB).[13],[14] OAB is defined as having urgency together with a noted frequency of urination of more than eight times a day, more than one occurrence of nocturia per day, and enuresis. A patient with general UUI will not meet these specific thresholds pertaining to frequency. Mixed UI can be a combination of any UI type. Patients with mixed UI usually have a combination of SUI and UUI.

Table 109-4

Urinary Incontinence Types and Characteristics

UI Types	Detrusor Muscle Activity	Urethral Sphincter	Pelvic Floor	Signs and Symptoms
UUI	Involuntary contractions caused by infection or neurologic conditions (detrusor overactivity)	No changes noted	No changes noted	A strong desire or urgency to urinate without the ability to defer the urge PVR < 50 mL Leakage is small.
SUI	No changes noted	No changes noted	Increased abdominal pressure with or without relaxed pelvic floor muscles Weakened pelvic floor muscles in females (childbirth, menopause)	Involuntary leakage during exertion (ie, physical activity) or from activities that apply pressure to the bladder (eg, coughing, laughing, sneezing) PVR < 50 mL Leakage is small.
OI	Weakened muscle tone (detrusor underactivity) secondary to nerve damage (eg, nerve damage from uncontrolled diabetes, spinal cord injury)	Obstructed urethra (eg, tumor, stone, enlarged prostate)	No changes noted	Complication of retention of urine when the bladder cannot empty completely, resulting in overdistension Experience urinary urgency/frequency, small voided volumes, urinary hesitation, poor/diminished flow rate, or nocturia PVR > 100 mL Leakage is large.
FUI	Physiology not typically altered	Physiology not typically altered	Physiology not typically altered	Inability to reach a toilet in time to void because of physical or cognitive impairment and/or external obstacles (ie, uses a wheelchair) PVR < 50 mL Leakage is small.

FUI, functional urinary incontinence; OI, overflow incontinence; PVR, postvoid residual volume; SUI, stress urinary incontinence; UI, urinary incontinence; UUI, urge urinary incontinence.

Clinical Presentation and Evaluation

CASE 109-1

QUESTION 1: H.K., an 83-year-old female with moderate dementia, was recently admitted to a nursing facility because of uncontrolled and worsening UI over the past 2 years. While at home, she was mainly being managed with use of absorbent pads and bladder training.

What objective and subjective data are needed to determine the type of UI contributing to H.K.'s UI?

The rationale for the clinical evaluation of H.K. is to classify the imbalance between bladder pressure and bladder sphincter resistance and, as a result, institute appropriate medical or surgical management of her UI.

Documentation of H.K.'s UI is accomplished most easily by keeping an incontinence record. Observations should be recorded every 2 hours regarding whether she is wet or dry, as well as associated symptoms or circumstances. A record maintained for 3 to 4 days will facilitate the assessment of the voiding pattern. Knowledge of the voiding pattern can be used to design bladder training programs and to detect iatrogenic causes (eg, diuretic ingestion, use of restraints). Successful bladder training relies on estimating when the bladder is full.

Physical examination, including a neurologic assessment, of H.K. is needed to determine the cause and classification of her UI. Clinical findings may identify specific pathophysiologic abnormalities. H.K. should have a thorough pelvic examination to determine the contribution of atrophic vaginitis, uterine prolapse, and bladder anatomy. Funneling of the bladder neck suggests stress incontinence, and palpation of the bladder suggests OI. The presence of physical restraints or musculoskeletal disability would suggest FUI.

H.K.'s bladder should be catheterized immediately after urination to determine residual urine volume. Alternatively, if a bladder ultrasound is available, the volume can be measured noninvasively. Volumes >50 to 100 mL in older adults are abnormal and may indicate retention due to obstruction or an adynamic detrusor muscle. If urinary retention is chronic, the patient may require clean

intermittent self-catheterization. Although urodynamic studies are widely recommended and used, little evidence suggests that these produce clinically useful data for institutionalized geriatric patients. A urinalysis, blood chemistries, renal function, and postprandial glucose tests should be performed. An abnormal urinalysis may suggest pathology (eg, infection) that can be managed medically. Urinary tract infection is common in the patient who is incontinent.

Case 109-1, Question 2: The incontinence record maintained by the nursing staff indicates that H.K. has to void >15 times a day, with varying amount of urine volume and including five incontinence episodes because she is unable to make it to the bathroom on time. She also has to wake up at least two times at night to void. She also has a small-volume leakage of urine upon sneezing and coughing. She is overweight, with a body mass index (BMI) of 28 kg/m^2. Her gynecologic history reveals three pregnancies resulting in vaginal delivery of >8-pound (3.63-kg) infants. Physical examination reveals atrophic vaginitis, no funneling of the bladder neck, and no bladder distension. H.K. does have a history of stroke. The urinalysis is normal, as are the blood chemistries. Postvoiding bladder scan revealed a residual urine volume of 40 mL. What is the pathophysiology and classification of H.K.'s incontinence?

Most neuropathic disease processes can change bladder function. As illustrated by H.K., a cerebrovascular accident is commonly associated with bladder dysfunction and incontinence in older adults. Neurologic injury above the level of the micturition center in the spinal cord, in most cases, results in bladder overactivity. Also, H.K.'s gynecologic history indicates the presence of pelvic floor weakness as the most likely cause of urinary leakage from increased abdominal pressure upon activities such as sneezing or coughing. H.K.'s UI is classified as mixed incontinence owing to underlying UUI, OAB, and SUI.

Nonpharmacologic Modalities

There are several nonpharmacologic measures that are beneficial and important to discuss with patients suffering from any type of UI. The first step is to educate patients about the appropriate use of

absorbent pads, dietary fluid management, avoidance of caffeine and other bladder irritants, weight loss, bowel regularity, and bladder training. Absorbent products should not be used for the mere convenience of caregivers, but to reduce the risks of UI-associated morbidity such as rashes, pressure ulcers, and skin infections. Females with UI should be counseled regarding fluid management, especially those with nocturnal or early-morning incontinence. Reduction in excessive fluid intake (eg, <2 L/day) and frequent bladder emptying can be useful strategies as well.[15] Obesity is an independent risk factor for developing UI, and females with obesity have a 4.2-fold greater risk of SUI than do those with a normal BMI.[16] Several trials show that moderate weight loss can improve UI symptoms in overweight females and females with obesity, especially SUI symptoms.[17],[18] Constipation or fecal impaction can worsen urinary retention; hence, bowel regularity can improve any UI type, specifically OI.

Bladder training, which includes interventions such as timed voiding, habit training, and prompted voiding, aims to increase the time interval between voiding using either a mandatory or a self-adjusted schedule, typically every 2 hours during waking hours. Bladder training also includes teaching urgency suppression strategies using relaxation and distraction techniques, self-monitoring, and reinforcement techniques. Although bladder training is typically used to treat UUI, it can also treat SUI and mixed UI.[19] A Cochrane review of limited and variable-quality evidence tentatively concluded that bladder training helps treat UI, including UUI, SUI, and mixed UI.[20]

Several other nonpharmacologic modalities are recommended for improving symptoms and slowing the progression of specific types of UI. Surgical interventions including sacral nerve stimulator or botulinum toxin injections have demonstrated benefits in UUI and OAB. High-quality evidence shows pelvic floor muscle training (PFMT) to be a more effective UI treatment than no active treatment.[21],[22] Supportive devices such as pessaries and prostheses in SUI are reserved for special situations, depending on patients' UI symptoms, cognitive and mobility status, and overall health status.

For OI, nonsurgical routes include either gender-specific external catheters or indwelling catheters.[14,23] For OI associated with severe benign prostatic hyperplasia (BPH) or prostate cancer in males, various surgical procedures such as transurethral resection of the prostate (TURP) or prostatectomy are considered to alleviate OI symptoms.[24] For FUI, the goal is to help improve a patient's ability to reach the restroom to minimize incontinence. Environmental interventions include the use of assistive devices such as restroom grab bars, raised toilet seats, and mobility assistance.[25] Other options include reviewing the proximity of the toilet or toilet substitutes (eg, bedside commode) and minimizing hazards (eg, rugs) in the restroom.

CASE 109-1, QUESTION 3: What nonpharmacologic therapy should be recommended for H.K.?

H.K. should have a comprehensive review of her medications completed to determine whether any of the current medications may be exacerbating or contributing to her UI symptoms. She should then be placed on a toileting schedule in which she is prompted to void every 2 hours. The nursing staff should continue to keep a bladder diary in which they record fluid intake and when she is wet and dry. This information can be used to tailor her toileting schedule to make sure H.K. has the best outcome while at the same time being practical, based on staffing at the institution. Because of H.K.'s moderate dementia, the teaching of pelvic floor muscle exercises may not be feasible. However, supportive devices such as pessaries and prostheses may be considered to alleviate SUI symptoms.

Drug Therapy

Pharmacotherapy options exist for each type of UI (**Table 109-5**). After comprehensive evaluation of the patient's symptoms and identifying the type of UI, it is essential to select pharmacotherapy options based on patient-specific factors such as preferred routes of

administration, therapeutic outcomes according to the patient's satisfaction and expectations, tolerability, affordability, and comorbid conditions.

Table 109-5
Drug Therapy for Urinary Incontinence

Type	Pharmacotherapy Options
Urge with or without overactive bladder	Oxybutynin Tolterodine Fesoterodine Trospium Darifenacin Solifenacin Mirabegron Vibegron Desmopressin (nocturia)
Stress	Vaginal estrogen cream (vaginal atrophy) Duloxetine (off label)
Overflow	Terazosin (BPH) Doxazosin (BPH) Tamsulosin (BPH) Alfuzosin (BPH) Silodosin (BPH) Bethanechol (urinary retention)

CASE 109-1, QUESTION 4: What drug therapy should be prescribed for H.K.?

H.K. has detrusor instability that may respond to antimuscarinic drug therapy if nonpharmacologic measures do not produce the desired results. Inhibition of the muscarinic receptors in the urinary bladder results in decreased urinary bladder contraction, increased residual urine volume, and decreased detrusor muscle pressure. The most important step in pharmacotherapy management of UI would be to identify the most efficacious antimuscarinic agent that the patient can tolerate best because of the many side effects associated with their use. A more selective antimuscarinic agent, such as solifenacin 5 mg once daily, would be ideal for H.K. to

minimize the impact on cognition through muscarinic receptor M1 blockade.

ANTIMUSCARINIC AGENTS

Antimuscarinics are the gold standard for UUI treatment and are U.S. Food and Drug Administration (FDA)-approved agents. Antimuscarinics block the parasympathetic muscarinic receptors M_2 and M_3 in the bladder to inhibit involuntary detrusor contractions. Systematic reviews showing clinical improvement and higher continence rates compared with placebo for reducing UUI support the efficacy of antimuscarinics; however, the effect was modest.[26,27] A clinically significant effect in UI is typically defined as a ≥50% reduction in daily incontinence episodes; however, the 2012 Agency for Healthcare Research and Quality report found that females reported improved quality of life and clinical success only when they had a ≥70% reduction in UI episodes per day.[27,28] Therefore, before initiating therapy, clinicians should discuss patients' expectations and educate them on what may be realistic and feasible regarding outcomes. Contraindications to using antimuscarinics include narrow-angle glaucoma, urinary retention, gastric retention, and decreased gastrointestinal (GI) motility disorders. Extreme caution is advised when considering prescribing antimuscarinics in patients with dementia or cognitive impairment.

Many antimuscarinics are available, including darifenacin, fesoterodine, oxybutynin, solifenacin, tolterodine, and trospium, as detailed in **Table 109-6**. As of 2021, five of the antimuscarinics are available generically (ie, oxybutynin immediate release [IR] and extended release [ER], tolterodine IR and ER, trospium IR and ER, solifenacin and darifenacin ER), whereas two agents remain brand name only (ie, transdermal oxybutynin gel and patch, fesoterodine). The transdermal oxybutynin patch (Oxytrol® for Women) can be obtained through a prescription but is now also available over the counter (OTC); no generic equivalent is currently available. Because high-quality evidence is lacking from head-to-head trials between specific agents, it is difficult to conclude whether these agents truly

have similar efficacy and safety profiles as currently published evidence suggests. No guidelines suggest one antimuscarinic over another. Selection of one antimuscarinic over another can be determined by a patient's tolerance to side effects of these agents because the incidence varies, as detailed in **Table 109-7**.

Table 109-6
Pharmacotherapy Options for Urge Urinary Incontinence/Overactive Bladder

Drug Name	Usual Dose (max)	Renal Dose Adjustments	Hepatic Dose Adjustments	Dose Adjustments for CYP Interactions
Antimuscarinics				
Darifenacin ER (Enablex®)	7.5 mg daily (15 mg daily)	—	Moderate: 7.5 mg daily Severe: not recommended	Concurrent potent CYP3A4 inhibitors: max 7.5 mg daily
Fesoterodine ER (Toviaz®)	4 mg daily (8 mg daily)	CrCl <30 mL/minute/1.73 m^2: 4 mg daily	Severe: not recommended	Concurrent potent CYP3A4 inhibitors: max 4 mg daily
Oxybutynin IR	5 mg two or three times daily (5 mg four times daily) Older adults (≥75): initial dose 2.5 mg two or three times daily	—	—	—
Oxybutynin ER (Ditropan XL®)	5–10 mg daily (30 mg daily)	—	—	—
Oxybutynin TDS (Oxytrol®)	3.9-mg patch–1 patch twice weekly (applied every 3 or 4 days)	—	—	—
Oxybutynin gel (Gelnique®)	One sachet or one pump actuation (100 mg/g) once daily	—	—	—
Solifenacin (VESIcare®)	5 mg daily (10 mg daily)	CrCl <30 mL/minute/1.73 m^2: 5 mg daily	Moderate: 5 mg daily Severe: not recommended	Concurrent potent CYP3A4 inhibitors: max 5 mg daily
Tolterodine IR (Detrol®)	2 mg twice daily (may decrease to 1 mg twice daily)	CrCl <30 mL/minute/1.73 m^2: 1 mg twice daily	Significantly reduced function: 1 mg twice daily	Concurrent potent CYP3A4 inhibitors: max 1 mg twice daily
Tolterodine ER (Detrol LA®)	4 mg daily (may decrease to 2 mg daily)	CrCl 10–30 mL/minute/1.73 m^2: 2 mg daily CrCl <10 mL/minute/1.73 m^2: use not recommended	Mild to moderate: 2 mg daily Severe: not recommended	Concurrent potent CYP3A4 inhibitors: max 2 mg/day
Trospium IR®	20 mg twice daily Older adults (≥5): initial dose 20 mg daily	CrCl <30 mL/minute/1.73 m^2: 20 mg daily at bedtime	—	—
Trospium ER®	60 mg daily	CrCl <30 mL/minute/1.73 m^2: not recommended	—	—
β_3-Agonist				
Mirabegron (Myrbetriq®)	25 mg daily (50 mg daily)	CrCl 15–29 mL/minute/1.73 m^2 or eGFR 15–29 mL/minute/1.73 m^2: 25 mg daily CrCl <15 mL/minute/1.73 m^2 or eGFR <15 mL/minute/1.73 m^2: use not recommended	Moderate: max 25 mg Severe: not recommended	—
Vibegron (Gemtesa®)	75 mg once daily	eGFR <15 mL/minute/1.73 m^2: use not recommended	Mild to moderate: no adjustments Severe: not recommended	Vibegron may increase the serum concentration of digoxin

CrCl, creatinine clearance; CYP, cytochrome P450; eGFR, estimated glomerular filtration rate; ER, extended release; IR, immediate release.

Table 109-7

Comparison of Common Anticholinergic Adverse Effects for Agents Indicated for Urge Urinary Incontinence Treatment (% Incidence) and Use in Older Adult Populations

Drug Name	Dry Mouth	Constipation	Dizziness	Fatigue	Somnolence	Headache	Blurry Vision	BEERS List
Darifenacin ER	59	28	0	NR	NR	8	4	Yes
Fesoterodine ER	99	14	2	<1	NR	12	4	Yes
Oxybutynin IR	88	32	38	15	40	22	22	Yes
Oxybutynin ER	68	9	11	18	4	12	3	Yes
Oxybutynin TDS	10	5	4	NR	2	NR	2	
Oxybutynin gel	12	NR	NR	NR	NR	NR	<2	
Solifenacin	34	19	1	NR	NR	4	7	Yes
Tolterodine IR	50	10	4	4	3	10	8	Yes
Tolterodine ER	39	10	3	3	3	7	6	Yes
Trospium IR	33	11	NR	NR	NR	6	3	Yes

ER, extended release; IR, immediate release; NR, not reported; TDS, transdermal.

Oxybutynin chloride

Oral oxybutynin has been the gold standard treatment for UUI and OAB for many years because of its high potency; however, patient adherence is suboptimal in most cases, and discontinuation rates are high because of the adverse effect profile. Because oxybutynin is a tertiary amine anticholinergic compound and blocks central M_1 receptors, the potential for CNS toxicity increases as the dose is increased.[29] Oxybutynin is available as an oral IR tablet, an ER tablet, a transdermal system, and a topical gel. The ER formulation of oxybutynin, which has less first-pass metabolism and consequently less conversion to the active metabolite and less-frequent dosing, is better tolerated and accepted by patients than is the IR formulation.[30] The transdermal formulations of oxybutynin (gel and patch) have a more favorable adverse drug reaction (ADR) profile than do other agents in the class, and the gel is typically better tolerated than is the patch.[31]

Tolterodine tartrate

Tolterodine is a competitive muscarinic receptor antagonist that is relatively selective for M_2 and M_3 receptors. When tolterodine

became available and showed less peripheral muscarinic antagonism and a reduced ability to cross the blood–brain barrier, its use became more prevalent because of its better tolerance compared with oxybutynin. However, at therapeutic and clinically effective doses, tolterodine also causes cognitive impairment and rare adverse effects such as hallucinations.[32] Tolterodine has an extensive drug interaction profile because it is metabolized by cytochrome P450 (CYP) 2D6 and CYP3A4 isoenzymes. Concurrent use of potent CYP2D6 inhibitors (eg, bupropion, cinacalcet, fluoxetine, paroxetine, quinidine, duloxetine, sertraline, and terbinafine) or potent CYP3A4 inhibitors (eg, protease inhibitors, clarithromycin, erythromycin, telithromycin, ketoconazole, itraconazole, fluconazole, verapamil, diltiazem, and grapefruit juice) may increase tolterodine drug concentrations and the potential for ADRs. Although tolterodine can modestly prolong the QT interval, no clinical or electrocardiographic evidence was seen of significant cardiac adverse events in the group studied.[33] The onset of the pharmacologic action of tolterodine is <1 hour, and therapeutic efficacy is maintained during long-term treatment. Despite short terminal half-lives of 2 to 3 hours and 3 to 4 hours for tolterodine and its active 5-hydroxy metabolite, respectively, twice-daily dosing is effective because of the drug's long pharmacodynamic effects.

Fesoterodine

Fesoterodine is an antimuscarinic prodrug that is converted into the same active metabolite as that of tolterodine. The efficacy and safety of fesoterodine appear comparable to those of tolterodine.[34] In a short-term study, fesoterodine was better than was tolterodine ER 4 mg and placebo in reducing UUI episodes, micturitions, urgency, and improving health-related quality of life. However, fesoterodine caused more dry mouth (28% vs 13%) and constipation (4% vs 3%) than did tolterodine ER. It has been associated with higher discontinuation rates owing to adverse events (5% vs 3%).[35] Furthermore, fesoterodine is currently available as brand only and is thus more expensive.

Trospium chloride

Trospium is a quaternary ammonium antimuscarinic agent with relative selectivity for M_2 and M_3 receptors. The hydrophilic properties of trospium minimize the passage of the drug through the blood–brain barrier, thereby causing fewer CNS and cognitive adverse events.[36] No significant differences were found in urodynamic outcomes between trospium and oxybutynin in a 52-week study.[37] The reduction in 24-hour micturition frequency and urgency episodes at 26 and 52 weeks of treatment was also not significant. However, the incidence of dry mouth and GI adverse events was significantly lower in the trospium group. Trospium is excreted unchanged in the urine and can compete with drugs having a similar excretion pathway (eg, digoxin, metformin, and morphine). Although data are limited, one clinical trial showed lack of cognitive impairment with trospium when used in older adults because of its lesser degree of transport across the blood–brain barrier compared with oxybutynin.[38]

M_3 selective antimuscarinics

Two antimuscarinic tertiary amines, darifenacin and solifenacin, are currently available with an indication for use in UUI or OAB. Each agent has shown selectivity for M_3 receptors within the detrusor muscles.[39] Antagonism of M_1 receptors located in the brain, which are primarily responsible for causing cognitive impairment in older adults associated with antimuscarinics, is minimal with either of these agents; thus, their M_3 selectivity is favorable.[40],[41] No studies have assessed the effects of solifenacin on cognition. Both agents are now available as generic and are cost-effective. A pooled analysis of three 12-week, double-blind, placebo-controlled trials (N = 1059) demonstrated that darifenacin reduced the median number of incontinence episodes per week ($P > .01$) versus placebo.[42] In clinical trials, solifenacin showed a significant reduction in the symptoms of urinary frequency, urgency, and urge incontinence compared with placebo.[43],[44] Safety concerns with solifenacin include

an increased risk of QT interval prolongation in patients with a known history of QT interval prolongation or patients who are taking medications known to prolong the QT interval.

β-ADRENERGIC AGONISTS

Mirabegron and vibegron are β-agonists that activate the β_3-adrenergic receptors in the detrusor muscle, which leads to muscle relaxation and increased bladder capacity. Both agents are FDA approved for the treatment of OAB and UUI (included in Table 109-6).

In a meta-analysis of phase III trials, mirabegron significantly reduced urge incontinence episodes compared with placebo (standardized mean difference −0.44; 95% confidence interval [CI], −0.59 to −0.29).[45] In a prospective cohort study of 354 females taking mirabegron for OAB, over two-thirds discontinued therapy within 1 year, usually because of lack of efficacy (26%), although patients were more likely to continue taking mirabegron than antimuscarinics because of fewer adverse effects with mirabegron.[46] Mirabegron should be avoided in patients with uncontrolled hypertension (HTN) because a pooled analysis of patients older than 65 showed treatment-induced HTN in 10% to 14% in patients receiving 25 to 50 mg of mirabegron compared with 8% of patients receiving placebo.[47] Mirabegron should also be avoided in patients with glaucoma, cognitive impairment, end-stage renal disease, and significant liver impairment. No information exists regarding whether patients are more likely to adhere to mirabegron than to the antimuscarinics. If mirabegron is used concurrently with drugs with a narrow therapeutic index (eg, flecainide, propafenone) that are metabolized through the CYP2D6 pathway, dose adjustments will be needed because mirabegron is a moderate CYP2D6 inhibitor. In addition, if digoxin and mirabegron are used concurrently, digoxin therapy should be initiated at the lowest dose, and serum concentrations should be monitored to ensure efficacy and prevent toxicity associated with digoxin.

For individuals who are unable to swallow pills, vibegron tablets may be crushed and taken with food. In clinical trials, vibegron is not associated with HTN and may be preferred in patients who are hypertensive with poorly controlled blood pressure. Vibegron appears to be at least as effective as antimuscarinic agents with similar rates of adverse effects. A meta-analysis of three trials including >1700 patients that compared vibegron with antimuscarinic monotherapy reported similar outcomes on bladder symptoms including the mean number of micturition episodes, mean number of urgency episodes, mean number of urgency incontinence episodes, mean number of incontinence episodes, and discontinuation rates due to an adverse event were not statistically different between the drugs.[48] In the phase III trial comparing vibegron 75 mg with tolterodine 4 mg (ER) in 505 individuals, improvement in OAB wet symptoms was greater for vibegron.[49] At week 52 of treatment, more patients receiving vibegron experienced ≥75% reduction in UUI episodes (61% vs 54%) and more reported a 100% reduction (40% vs 34%) compared with those receiving tolterodine. Although patient discontinuation resulting from adverse effects was greater for tolterodine compared with vibegron (3.4% vs 1.5%, respectively), this difference was not statistically significant or clinically meaningful.

CASE 109-2

QUESTION 1: M.K., a 60-year-old female, has been diagnosed with SUI. What therapy would be appropriate for M.K.'s SUI?

M.K. should initially be educated on pelvic floor muscle or Kegel exercises. Nonpharmacologic modalities are considered first-line therapy for the management of SUI. Several methods have been effectively used to help patients identify and correctly exercise the pelvic floor muscles, including self-help books, biofeedback, electrical stimulation, and verbal feedback during physical examination by a physician. Once the pelvic floor muscles have been identified, M.K. should empty her bladder and sit or lie down. She should contract her pelvic floor muscles, holding the contraction

for 5 seconds, and then relax for 5 seconds. This should be repeated five times with a goal of 10-second contractions for M.K. She should practice these exercises three times a day. If M.K. is overweight or obese, she should be educated on the benefits of weight loss on improvement in SUI symptoms.

Duloxetine

Duloxetine is a serotonin and norepinephrine reuptake inhibitor that has shown efficacy in patients with stress incontinence. Duloxetine use is supported by the European guidelines and is approved for this indication in Europe; however, duloxetine currently lacks FDA approval. Duloxetine increases urethral tone during the storage phase by inhibiting norepinephrine reuptake. Duloxetine also treats depression, and although not FDA approved for the treatment of stress incontinence, it could be a reasonable option for a female with both depression and stress incontinence. A meta-analysis of nine trials including 3063 females predominately with stress incontinence showed that patients treated with duloxetine had a reduction in the incontinence episode frequency by ~50%; however, the absolute reduction (10.8% vs 7.7%) in incontinence episodes was small, suggesting that any benefits would be modest. Adverse effects were common, with 71% of patients treated with duloxetine reporting side effects and approximately one in eight patients discontinuing treatment.[48] Duloxetine reduced incontinence episode frequency, improved the voiding interval process, and enhanced quality of life at the 75-mg/day dose compared with placebo in a 12-week double-blind, randomized, placebo-controlled clinical trial. However, duloxetine was associated with nausea in about 40% of the patients.[49] The most common adverse effect with duloxetine is nausea, which tends to resolve with time. The clinical effects of duloxetine appear to be modest and need to be weighed against the risk of adverse events. Patients' current medication profiles should be screened for agents that can increase the risk of serotonin syndrome in combination with duloxetine (eg, selective serotonin reuptake inhibitors, tramadol) and drugs that can inhibit CYP1A2 and

increase duloxetine serum concentrations (eg, amiodarone, ciprofloxacin, cimetidine). Because of mixed-quality evidence indicating only a modest benefit of duloxetine in treating SUI compared with high discontinuation rates owing to adverse events, it is imperative to educate patients and involve them in the decision to initiate duloxetine therapy.

Estrogens

Topical estrogen therapy may be beneficial in females with coexisting atrophic vaginitis and SUI. Topical or vaginal estrogens provide localized treatment of atrophic vaginitis and may increase urethral tone. Localized estrogen treatment is well tolerated and provides minor benefit (risk ratio [RR] 0.74; 95% CI, 0.64–0.86) for incontinence in postmenopausal females but does not improve quality of life.[27] Topical estrogen therapy options include conjugated estrogen vaginal cream (Premarin®) 0.5 g three times weekly or the estradiol vaginal ring (Femring®) inserted every 3 months. Adverse effects include vaginal spotting, breast tenderness, and nausea. If recommended, estrogen therapy should be used at the lowest dose and for the shortest time possible to prevent long-term ADRs and potential risk of endometrial carcinoma. The use of estrogen in the treatment of SUI requires further study.

α-Adrenergic agonists

α-Adrenergic agonists such as pseudoephedrine and phenylephrine, which stimulate urethral smooth muscle contraction, may be modestly beneficial in reducing SUI symptoms. Limited evidence suggesting the use of α-adrenergic agonists primarily consists of studies of phenylpropanolamine, which is no longer available in the United States. Adrenergic agonists are no longer recommended because they are only mildly efficacious compared with placebo and have a high rate of adverse effects.[50] Several studies have evaluated whether the clinical and urodynamic effects of a combination of estrogen and an α-adrenergic receptor agonist exceed those of the individual therapies for SUI. In general, combination therapy has

resulted in better clinical and urodynamic responses than has monotherapy.[51] If combination therapy is used or recommended, patients should be educated on the associated adverse effects, including dizziness, insomnia, headache, tachycardia, and increased blood pressure. Patients should also be screened for underlying cardiovascular conditions and any endocrine conditions, which may be worsened by the adrenergic agonism induced by pseudoephedrine or phenylephrine.

Case 109-2, Question 2: M.K. has incomplete resolution of her stress incontinence symptoms. Physical examination indicates urogenital atrophy. What are the pharmacologic options for stress incontinence?

M.K.'s incomplete resolution of stress incontinence symptoms is probably caused by urogenital atrophy. She would respond well to an intravaginal estrogen cream, which will improve local blood flow and dryness. An estrogen cream such as estradiol should be prescribed at a dose of 0.5 g of cream three times a week. The combination of local estrogen therapy and pelvic floor muscle exercises should eliminate M.K.'s symptoms.

Desmopressin

Desmopressin (DDAVP®) was approved in March 2017 in the United States for the treatment of nocturia in adults who awaken at least two times per night to void and is one of the key symptoms of OAB. DDAVP® is a synthetic vasopressin analog that is available in intranasal (Noctiva®) as well as sublingual (Nocdurnal®) formulation. Before considering therapy with DDAVP®, it is imperative to ensure that the patient is not at risk for hyponatremia because this is one of the most common side effects of this product and necessitates dose adjustment. The dose of intranasal desmopressin for patients who are not at risk for hyponatremia is 1.66 µg in either nostril 30 minutes before bedtime. In patients who are at risk for hyponatremia, the starting dose is 0.83 µg in either nostril 30 minutes before bedtime. The dose may be increased to 1.66 µg after at least 1 week of

therapy.[52] The dose of the sublingual formulation is 27.7 µg (for females) or 55.3 µg (for males) once daily 1 hour before bedtime.[53] Owing to several other contraindications, including polydipsia, primary nocturnal enuresis, concomitant use of loop diuretics or glucocorticoids (systemic or inhaled), renal impairment, syndrome of inappropriate antidiuretic hormone secretion, illness that can cause fluid or electrolyte imbalance, moderate-to-severe heart failure, and uncontrolled HTN, use of this product is limited.

OVERFLOW INCONTINENCE

The most common cause of OI in males is BPH or malignant prostatic hyperplasia; hence, proper management of BPH is essential to resolve urinary symptoms of OI. If a patient with OI is identified to have urinary retention secondary to neurogenic atony of the bladder, a cholinergic agent, bethanechol, may be considered. As a cholinergic agent, bethanechol increases bladder muscle tone causing contractions that initiate urination, although well-done studies have not provided strong evidence for its benefits.[54] Bethanechol is initially administered at the lowest dose of 5 to 10 mg every hour up to a maximum dose of 50 mg and then transitioned to 10 to 50 mg three to four times daily for maintenance. Common adverse effects of bethanechol include flushing, tachycardia, abdominal cramps, and malaise.

BENIGN PROSTATIC HYPERPLASIA

BPH is defined by the American Urological Association as “a histologic diagnosis that refers to smooth muscle and epithelial cell proliferation within the prostatic transition zone.”[55] The histologic evidence of BPH may be prevalent in ~80% of older males; however, only 60% at least age 60 years develop symptomatic disease.[56] This prevalence increases to ~78% in males 80 years and older.[57] The term *benign prostatic hypertrophy* often is used inappropriately

because the prostate gland pathology results from hyperplasia rather than from hypertrophy.

CASE 109-3

QUESTION 1: G.M., a 69-year-old male, presents to the emergency department with increasing difficulty initiating urination, a significant decrease in the force of his urinary stream, occasional midstream stoppage, and postvoid dribbling. He states that these symptoms started 4 days ago and have been persistent. Physical examination reveals abdominal distension and tenderness. Digital rectal exam confirmed a severely enlarged, firm, and rubbery prostate gland without nodules or undue hardness. G.M. reports urinary frequency of 8 to 10 times per day and 4 to 5 times per night. G.M. indicates that upon urination, he notices weak stream dribbling and does not feel relieved. Laboratory findings are as follows:

Blood urea nitrogen (BUN), 45 mg/dL
Serum creatinine (SCr), 3.2 mg/dL
Serum prostatic acid phosphatase, 3 units/L
Serum prostate-specific antigen (PSA), 7.1 ng/mL
A urethral catheter was inserted, and 900 mL of urine was obtained. G.M. subsequently was scheduled for a urologic workup.

What is the pathophysiologic basis for G.M.'s symptoms?

Pathophysiology

There is both a static and a dynamic component to prostate enlargement. The static component increases the prostate size by smooth muscle cell proliferation in the prostate stroma, whereas the dynamic component contributes to an enlarged prostate through an increase in smooth muscle tone in the prostate and bladder neck. Static factors related to age and androgen-induced prostate enlargement cause physical block at the bladder neck and obstruct urinary flow. After the first growth spurt at the time of puberty when prostate size starts to increase, a second growth spurt begins and continues at age 40 and thereafter. During this phase, the prostate may enlarge up to quadruple the size and lead to symptomatic disease. In the prostate, type II 5α-reductase enzyme converts testosterone into dihydrotestosterone (DHT), which is responsible for

growth and enlargement of the prostate. Despite the age-related decline in testosterone level, intraprostatic DHT levels are maintained. In the periphery, the ratio of testosterone to estrogen declines, and estrogen is theorized to induce androgen receptors and contribute to growth of the stromal portion of the prostate. Dynamic factors relate to exaggerated α-adrenergic tone that leads to smooth muscle contraction, compression of the urethra, and reduced urinary bladder emptying. Normally, the ratio of stromal to epithelial tissue in the prostate is 2:1, which is exaggerated to 5:1 in an enlarged prostate. Stromal tissue comprises the α1-adrenergic receptors that are stimulated as a result of the enlargement.

Case 109-3, Question 2: What subjective and objective findings in G.M. are associated with BPH?

Clinical Presentation and Evaluation

Etiologies stemming from static or dynamic factors facilitate in identifying and evaluating patient's BPH-related urinary symptoms. Symptoms of BPH can be categorized as obstructive and irritative and are collectively referred to as *lower urinary tract symptoms (LUTS)*.

Obstructive symptoms are associated with reduced bladder emptying and result in straining to void, weak urine flow or stream, hesitancy, sensation of incomplete bladder emptying, and postvoid urinary dribbling. The common obstructive symptom of decreased force and size of urine stream is caused by urethral compression from prostate gland hyperplasia. Hesitancy, another obstructive symptom, is the result of the bladder detrusor muscle taking a longer time to generate the initial increased pressure to overcome urethral resistance. Urinary stream intermittency is caused by the inability of the bladder detrusor muscle to sustain the increased pressure until the end of voiding. Terminal dribbling and incomplete emptying occur for the same reason, but also may be caused by obstructive prostatic tissue at the bladder neck, causing a "ball-valve" effect.

Irritative symptoms result from long-standing bladder neck obstruction and result in urgency, frequency, and nocturia. Incomplete emptying of the bladder results in shorter intervals between voiding, thus resulting in frequency. Also, a large prostate gland provokes the bladder to trigger a voiding response more frequently. This response is more pronounced if the prostate is growing intravesically and compromising the bladder volume. The bladder detrusor muscle becomes hypertrophied as a result of the greater bladder residual urine volume, which can result in increased detrusor muscle excitability. Clinically, this excitability may result in bladder instability. The symptoms of urinary frequency are more pronounced at night because cortical inhibitions are lessened and bladder sphincter tone is more relaxed during sleep.

Approximately 17% to 20% of patients with symptomatic BPH suffer from complications including acute urinary retention, suprapubic pain from distended bladder, recurrent urinary tract infections, hematuria, bladder stones, bladder diverticula, and renal failure. Patients with a prostate gland volume of 30 to 40 mL or PSA of ≥1.4 ng/mL (μg/L) are especially more prone to complications of BPH.[58–60] Acute urinary retention in BPH can occur as a result of increasing size of the prostate gland. Independent of gland size, drugs may precipitate acute urinary retention. Drugs, such as alcohol, anticholinergic agents, α-adrenergic agents, and neuroleptics, have all been associated with acute urinary retention in males with BPH. Commonly, when advanced BPH is present, acute urinary retention is exacerbated if the patient does not void at the first sign of urgency.

UI is not a common symptom of BPH. With advanced BPH, a large residual volume of urine in the bladder weakens the bladder sphincter and allows the escape of small amounts of urine when the bladder is full. Because the residual bladder volume increases, the ureters will dilate, resulting in stasis of urine in the ureters. The end result may be ascending hydronephrosis caused by the transmission of high pressure to nephrons, which produces renal damage (**Table 109-8**). This can account for abdominal discomfort and flank pain during voiding and ascending urinary tract infections.

Table 109-8
American Urological Association Urinary Symptoms Score/International Prostate Symptom Score

Questions to Be Answered	Not at All	Less Than 1 Time in 5	Less Than Half the Time	About Half the Time	More Than Half the Time	Almost Always	Your Score
1. Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5	
2. Over the past month, how often have you had to urinate again <2 hours after you finished urinating?	0	1	2	3	4	5	
3. Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
4. Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5	
5. Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5	
6. Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5	
7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0 (None)	1 (One time)	2 (Two times)	3 (Three times)	4 (Four times)	5 (Five or more times)	
Sum of Numbers (American Urological Association Symptom Score):							
Total score: 0–7: Mild symptoms 8–19: Moderate symptoms 20–35: Severe symptoms							
Quality of life because of urinary symptoms	Delighted	Pleased	Mostly satisfied	Mixed-about equally satisfied and unsatisfied	Mostly dissatisfied	Unhappy	Terrible
If you were to spend the rest of your life with your urinary condition the way it is now, how would you feel about that?	0	1	2	3	4	5	6

The American Urological Association (AUA) symptoms score and the International Prostate Symptom Score (IPSS) use the same questions and scale. The IPSS additionally includes the last disease-specific quality of life question.

The Measurement Committee of the American Urological Association. *J Urol*. 1992;148(5):1549–1557. © 1992 The American Urological Association Education and Research, Inc.

To identify the most bothersome symptoms and select appropriate drug therapy, the patient's perception and severity of BPH should be evaluated using validated instruments. The Multidisciplinary Measurements Committee of the American Urologic Association (AUA) also has published a urinary symptom index (see Table 109-8) for BPH.[61] The index is useful to assess the baseline severity of BPH, disease progression, and effectiveness of different therapies (**Table 109-9**). The AUA Symptom Index (AUA-SI) allows comparison among therapies and is the preferred questionnaire for BPH research. It has been validated through internal consistency, reliability, constructive reliability, test–retest reliability, and criterion reliability.[62]

Table 109-9
Categories of Benign Prostatic Hyperplasia Disease Severity Based on Symptoms and Signs

Disease Severity	AUA Symptom Score	Typical Symptoms and Signs
Mild	≤7	Asymptomatic Peak urinary flow rate <10 mL/second PVR urine volume >25–50 mL
Moderate	8–19	All of the abovementioned signs plus obstructive voiding symptoms and irritative voiding symptoms (signs of detrusor instability)
Severe	≥20	All of the abovementioned plus one or more complications of BPH

AUA, American Urological Association; BPH, benign prostatic hyperplasia; PVR, postvoid residual volume.

G.M. presents with classic symptoms of BPH, including obstructive and irritative symptoms. The increasingly severe symptoms culminated in an episode of acute urinary retention, as evidenced by inability to void and lower abdominal discomfort. Objective symptoms associated with G.M.'s BPH include (a) abdominal tenderness; (b) the finding of an enlarged bladder; (c) an enlarged, firm, and rubbery

prostate gland; and (d) a return of 900 mL of urine via the urinary catheter. The normal serum acid phosphatase, slightly elevated PSA, and digital rectal examination of the prostate suggest that G.M. does not have prostatic carcinoma at this time. The PSA result for G.M. is slightly above the upper limit for his age. As such, he should have a transrectal ultrasound (TRUS) to determine the prostate gland volume and, hence, the PSA density. Once the prostate gland volume is determined, the significance of his PSA level of 7.1 ng/mL can be determined. The elevated BUN and SCr may suggest hydronephrosis as a result of his BPH.

CASE 109-3, QUESTION 3: What additional tests should be completed to evaluate G.M.?

URINALYSIS

Because patients with BPH also may have a urinary tract infection, a urinalysis with microscopic examination is essential. It is mandatory that G.M. provide a urine specimen for urinalysis before the digital rectal examination of the prostate gland because examination of the prostate causes prostatic secretions to be expelled into the urethra, which may contaminate the urine specimen and make it difficult to determine the source of an infection. The presence of white blood cells and bacteria in the urine necessitates a workup for infection. Similarly, hematuria requires a workup for urinary tract pathology other than BPH. Because BPH also can cause hydronephrosis, renal function and serum electrolytes should be evaluated.

DIGITAL RECTAL EXAMINATION

A serum PSA followed by a digital rectal examination of the prostate remains a fundamental part of evaluating a male with BPH. The prostate examination should determine the size, shape, consistency, and nodularity of this gland. Prostatic hyperplasia results in a large, palpable prostate with a smooth mucosal surface rectally. The discernment of the right and left prostate lobes is lost in BPH. The digital rectal examination of a patient with BPH commonly finds

asymmetry of the prostate, with one side being larger than the other. Prostatic enlargement can be in both an anteroposterior and a superoinferior direction. As a result, on digital rectal examination, the upper extent of prostate hyperplasia is not palpable. Occasionally, the degree of enlargement felt by digital rectal examination may be misleading because a substantial portion of enlargement may be intravesicular. The consistency of the gland may be soft or firm, depending on the predominance of glandular or fibromuscular elements.[63] The presence of firm-to-hard nodules, irregularities, induration, or a stony, hard prostate suggests possible prostate cancer. In those cases in which the prostate gland size or shape may be questioned, the patient should have a TRUS to determine the gland volume.

PROSTATE-SPECIFIC ANTIGEN

PSA correlates reasonably well, on average, with prostate weight owing to benign prostate glandular hyperplasia.[61] Males ages 40 years and older with at least a 10-year life expectancy have been encouraged to have an annual measurement of serum PSA and a digital rectal examination as a basic screen for prostate cancer and to monitor the growth of the prostate gland. PSA is not necessary for the diagnosis of BPH; however, it helps determine whether disease-modifying therapy options are indicated.[64]

Urinary flow rate

Urinary flow rate (UFR) is the rate of urine flow out of the bladder and typically should be at least 10 mL/second. It is a noninvasive objective measure of bladder emptying, and if reduced, indicates failure of bladder emptying and risk of acute urinary retention.[65]

Postvoid residual volume

PVR is another objective measure of bladder emptying that is defined as volume of urine remaining in the bladder after complete voiding. Normal PVR levels are defined variably; however, a PVR of

≥25 to 50 mL implies failure of bladder emptying, whereas >100 mL indicates worsening of BPH symptoms.[66]

Drug Therapy

In the United States, AUA guidelines on management of BPH primarily facilitate goal setting and treatment decisions.[61] The AUA recommends that goals of BPH management should include symptom improvement, as evidenced by a minimum of a three-point decrease in the AUA-SI, reducing the risk of complications, delaying the need for surgical intervention, and preventing progression of the disease. AUA-guided BPH management includes watchful waiting, pharmacotherapy, and surgical interventions (**Table 109-10**). Selection of pharmacotherapy can be based on the efficacy and clinical impact of each of the drug classes on symptoms and progression of BPH (**Table 109-11**).

Table 109-10
Management of Benign Prostatic Hyperplasia

Disease Severity	AUA-SI Score	AUA Recommended Management
Mild	≤7	Watchful waiting Nonpharmacotherapy interventions Follow-up in 6–12 months
Moderate	8–19	Pharmacotherapy options to consider: 1. Small prostate, low PSA level: α_1-adrenergic antagonists 2. Large prostate, increased PSA level: α_1-adrenergic antagonists + 5α-reductase inhibitors 3. With erectile dysfunction: α_1-adrenergic antagonists, phosphodiesterase inhibitors, or both 4. With irritative symptoms: α_1-adrenergic antagonists + antimuscarinics, or + mirabegron
Severe	≥20	Minimally noninvasive surgery or prostatectomy if complications are present

AUA, American Urological Association; AUA-SI, American Urological Association Symptom Index.

Table 109-11
Comparison of Drug Classes for Benign Prostatic Hyperplasia Management

	α- AA	5α-RI	PDE-5Is	ACHs	β3-AA
Decreases Prostate Size	No	Yes	No	No	No
Halts Disease Progression	No	Yes	No	No	No
Peak Onset	1–6 weeks	3–6 months	4 weeks	1–2 weeks	2–8 weeks
Efficacy in Relieving Irritative Symptoms	++	++ (if enlarged prostate)	+	0	0
Frequency of Dosing	Once or twice a day	Once a day	Once a day	Varies	Once a day
Decreases PSA	No	Yes	No	No	No

ACH, anticholinergic; α-AA, α1-adrenergic receptor antagonist; 5α-RI, 5α-reductase inhibitor; β3-AA, beta-3 adrenergic agonist; PDE-5Is, phosphodiesterase type 5 inhibitor.

CASE 109-3, QUESTION 4: What drug therapy should be prescribed to treat G.M.'s prostatic hyperplasia?

G.M. most likely will be scheduled for a TURP because he presents with acute urinary retention and hydronephrosis owing to a moderately enlarged prostate gland (ie, >40 g in size). He should be started and maintained on an α_1-adrenergic receptor antagonist to reduce the tension of the bladder neck, the prostate adenoma, and the prostatic capsule. Similarly, he should receive a 5α-reductase inhibitor (5ARI) to induce atrophy of the prostate gland and halt the progression of the disease.

The prostatic capsule and hyperplastic prostate have plentiful α_{1A}-adrenergic receptors. The three known subtypes of the α_1-adrenergic receptor are α_{1A}, α_{1B}, and α_{1D}. Inhibiting the α_{1A}-adrenergic receptors can reduce the smooth muscle tone of the prostatic urethra, thereby reducing the functional component of urethral constriction and obstruction.

α_1-ADRENERGIC ANTAGONISTS

Indicated for initial therapy in patients with symptomatic BPH, this drug class exerts its effects by targeting the dynamic factors and by relaxing smooth muscle in the bladder neck, prostate capsule, and prostatic urethra. First-generation α-adrenergic agents, such as phenoxybenzamine, have been replaced by the second-generation nonselective α1-adrenergic antagonists, including terazosin and doxazosin and third-generation uroselective α_{1A} antagonists, including tamsulosin and silodosin. Alfuzosin is a second-generation agent; however, it has clinically significant uroselective effects. Prazosin is also a second-generation agent; however, owing to multiple dosing frequency and higher risk factor for cardiovascular side effects, it is not recommended for use per AUA guidelines.

NONSELECTIVE α_1-ADRENERGIC ANTAGONISTS

Terazosin

In most patients, the dose of terazosin should be started at 1 mg once daily at bedtime and titrated over several weeks to 5 to 10 mg once daily to obtain desired results. Orthostatic hypotension may occur in the beginning days of therapy or during dosage adjustment periods. In patients who stop their terazosin therapy for ≥2 days, therapy should be reinstituted cautiously to avoid the “first-dose” adverse effect of syncope. Bedtime administration may minimize orthostatic hypotension that is associated with the “first-dose” effect of these agents.

Terazosin has significantly reduced obstructive symptoms and improved UFRs at doses of 1 to 5 mg/day.[62] Terazosin has demonstrated sustained improvement in BPH symptom scores for a 30-month period. Only 10% of the patients experienced treatment failure. In this long-term study, the systolic blood pressure in normotensive and hypertensive patients was decreased by 4 and 18 mm Hg, respectively. Apparently, terazosin typically only lowered the blood pressure significantly in patients with hypertension.

Doxazosin

Doxazosin originally was prescribed primarily for HTN and currently is not considered a first-line antihypertensive agent.[62] HTN and BPH are linked by the sympathetic nervous system. As with terazosin, doxazosin improves UFRs and symptoms in patients with BPH. These effects have been demonstrated in controlled clinical studies, within weeks, and for the long term.

Doxazosin should be started at 1 mg/day. After 1 to 2 weeks, the dose can be increased over several weeks to 8 mg/day. Similar to other nonselective agents in this drug class, the first dose should be taken at bedtime to minimize lightheadedness and syncope (the first-dose effect), and the blood pressure of the patient should be monitored periodically during therapy. Most patients require between 4 and 8 mg/day for effective control of the urinary symptoms of BPH. Dosages >4 mg/day are associated with a greater frequency of dizziness, orthostatic hypotension, and syncope.[67]

UROSELECTIVE α_1-ADRENERGIC ANTAGONISTS

Tamsulosin

Tamsulosin and its metabolites are more specific for the prostatic α_{1A}-adrenergic and less specific for the vascular α_{1A}-adrenergic receptors responsible for orthostatic hypotension. Consequently, no need exists to titrate tamsulosin to the recommended daily dose range of 0.4 to 0.8 mg. Coadministration of tamsulosin with antihypertensive agents does not require dosage adjustment of the antihypertensives. Tamsulosin is very effective in treating bladder outlet obstruction associated with BPH.[68]

More than 90% of tamsulosin is absorbed after oral administration of a 0.4-mg dose under fasting conditions. It is recommended to administer the dose of tamsulosin 30 minutes after the same meal daily. Administration with food decreases the bioavailability by 30% and increases the time to peak plasma concentration. Tamsulosin is hepatically metabolized by CYP3A4 and CYP2D6. Impaired renal function increases the total tamsulosin plasma concentration by ~100% during steady state. However, active unbound drug levels are not affected; thus, renal dose adjustment is not required. Tamsulosin

appears to reduce mean ejaculatory volume in 90% of patients. As with all α_1-adrenergic receptor antagonists, tamsulosin does not affect the PSA and must be taken indefinitely to maintain its therapeutic effect.[68–72]

Alfuzosin

Alfuzosin is available as an ER tablet that has a recommended daily dose of 10 mg given after the same meal each day. Higher concentrations in the prostate after usual doses, lack of peak serum levels, and fixed dosing are believed to contribute to its clinical uroselectivity.[73],[74] A lack of penetration of alfuzosin into the brain has been hypothesized to contribute to decreased CNS effects such as somnolence. It displays a lower rate of hypotensive effects than do doxazosin and terazosin. Unlike tamsulosin, alfuzosin will not cause ejaculatory dysfunction; the incidence is comparable to placebo.[71]

Silodosin

Silodosin has a strong affinity for prostatic tissue and is 20 times more “uroselective” than is tamsulosin.[75] Silodosin is available as 4- and 8-mg capsules, and the recommended dose is 8 mg once daily. In patients with a creatinine clearance of <50 mL/minute, the dose should be decreased to 4 mg once daily. The most common side effect of silodosin is retrograde ejaculation.

PHOSPHODIESTERASE-5 INHIBITOR

This drug class is indicated in males with BPH-related symptoms and ED. Phosphodiesterase-5 inhibitors (PDE-5Is) have demonstrated efficacy in improving LUTS without significant reduction in objective measures such as UFR.[76] A more recent Cochrane review of 16 randomized controlled trials (RCTs) found that compared to placebo or α-blockers, PDE-5Is reduce symptom scores slightly; however, they are associated with increased ADRs.[77] The study also found that PDE-5Is were not superior to α-antagonists and combination therapy of the two drug classes did not

result in any greater benefit. PDE-5I use is associated with rare adverse effects including headache, flushing, dyspepsia, nasal congestion, back pain, myalgias, and sinusitis. There is an increased risk of hypotension in patients also using certain α-adrenergic antagonists.

Tadalafil

Tadalafil is a selective PDE-5I and was shown to improve BPH symptoms compared to placebo; it is FDA approved for use in males with BPH and ED at 5 mg/day dose. Tadalafil should be taken at the same time every day without regard to meals. Evidence is lacking to support use of tadalafil in combination with α-adrenergic receptor antagonists and concurrent therapy may increase the risk of low blood pressure. Similarly, patients on antihypertensives, nitrates, or drinking 5 or more units of alcohol are also at increased risk for hypotension with tadalafil. Additional information on tadalafil can be found under the section on Pharmacotherapy for ED later in this chapter.

5α-REDUCTASE INHIBITORS

The 5ARIs block one of the three isozymes of 5α reductase and prevent the conversion of testosterone (T) to DHT. Such inhibition of 5α reductase results in symptomatic relief in patients experiencing LUTS due to prostate enlargement; however, its primary benefit is not acute symptom management. Owing to its unique mechanism of action, 5ARIs halt BPH progression by reducing prostate size and decreasing PSA levels. Utility of 5ARIs in patients with >35-g prostate size has been proved in the Medical Therapy of Prostatic Symptoms (MTOPS) study.[78] It is important to note that the benefits of 5ARI therapy may not be apparent for 6 to 12 months because the impact on prostate size and PSA levels takes months of therapy to be significant. Nonetheless, this drug class does reduce or delay the need for invasive management modalities including prostate surgery.

A few concerns and ADRs associated with use of 5ARIs may limit their use. The most concerning ADR of 5ARIs is sexual dysfunction,

including ED, decreased libido, ejaculatory dysfunction, gynecomastia, and breast tenderness. These ADRs are known to be dose related and reversible upon cessation of therapy. A conflicting finding that 5ARIs can play a role in reducing the risk of prostate cancer has been challenged because of the lack of clear benefits; hence, prophylactic use of this drug class for this theoretical benefit is not recommended. Similarly, increased risk of high-grade tumors with concurrent use of 5ARIs also lacks support.

EFFECT OF ANDROGEN SUPPRESSION ON PROSTATE-SPECIFIC ANTIGEN

Case 109-3, Question 5: G.M. has an annual PSA test. Will androgen suppression alter his results?

Antiandrogen treatment of BPH could possibly adversely affect the interpretation of the PSA screening test for prostate cancer. Concern related to the utility of PSA levels as a marker for prostate cancer while a patient is on 5ARI therapy is legitimate because serum PSA levels are suppressed by ~50% with 5ARIs. To ensure that suppressed PSA levels are not mistaken as "normal" PSA levels in regard to prostate cancer monitoring, it is recommended to obtain baseline PSA before initiating 5ARI therapy. Retest at 6 months and consider that level the new baseline, and then continue monitoring for increases in levels thereafter compared to the new baseline level. Nevertheless, patients receiving a 5ARI should have (a) a digital rectal examination of their prostate periodically, (b) the PSA level measured, and (c) any suspicious findings investigated immediately.[102] Androgen suppression therapy is not contraindicated in BPH solely on the basis of its effect on serum PSA levels.[64]

Finasteride

Finasteride is a selective 5ARI that specifically inhibits 5α-reductase type 2 isozyme and is FDA approved for use in males with BPH 5-mg once-daily dosing. Finasteride's efficacy in improving symptoms,

urinary flow, and DHT levels in patients with enlarged prostates, especially those with prostates >40 g has been demonstrated in several trials. Also, the efficacy and improvements from finasteride therapy were sustained for >4 years.[79–81]

Dutasteride

Dutasteride is a nonselective 5ARI that inhibits both type 1 and 2 5α-reductase isoenzymes and is FDA approved for use in males with BPH at 0.5-mg once-daily dosing. An advantage of dutasteride compared with finasteride is the additional inhibition of 5α-reductase (type 1) in the peripheral tissues, which produces a further decline in serum DHT. However, in a head-to-head trial of finasteride and dutasteride, no significant difference in prostate volume reduction and improvements in urine flow rates was found between the two drugs.[82] Clinical trials and meta-analysis provide robust findings to support benefits of dutasteride in improving symptoms, reducing UFRs, decreasing prostate volume, and reducing the risk of acute urinary retention and the need for surgical BPH intervention.[83],[84]

Combination therapy

Certain patients with BPH may be appropriate candidates for combination therapy. For quick symptomatic relief of obstructive symptoms, α_1-adrenergic receptor antagonists are first line and must be initiated. However, for symptomatic patients with an enlarged prostate, adding a 5ARI is indicated. Even though 5ARIs may provide symptomatic relief, it could take 6 to 12 months to improve symptoms. As a result, combination therapy is most appropriate for such patients. This strategy has been supported by the MTOPS and Combination of Avodart and Tamsulosin (CombAT) trials.[85],[86] The MTOPS trial studied 3047 males with moderate-to-severe BPH and demonstrated that combination therapy was superior to monotherapy with either an α_1-adrenergic antagonist or a 5ARI in improving symptoms and UFR. The risk of clinical progression of BPH was reduced by 39% in patients treated with doxazosin alone, by 34% in

patients treated with finasteride alone, and by 66% in patients treated with combination therapy. The CombAT trial studied 4844 males with risk factors for BPH progression such as larger prostates (>30 g) and higher serum PSA concentrations (1.5–10 µg/L). Combination therapy reduced the relative risk of acute urinary retention or BPH-related surgery by 65.8% compared with tamsulosin alone and by 19.6% compared with dutasteride alone. In addition, for those patients who completed the study, the mean change in the International Prostate Symptom Score from baseline to year 4 was significantly higher for the combination therapy compared with tamsulosin or dutasteride alone. Adverse drug events are more common with combination therapy, but study withdrawal rates were <5% and similar among treatment groups. A combination product of dutasteride 0.5 mg and tamsulosin hydrochloride 0.4 mg is commercially available.

CASE 109-3, QUESTION 6: G.M. asks whether there are nonprescription treatments that are effective for BPH available. What OTC medications are available for prostate disorders?

Two agents, saw palmetto and pygeum, have been promoted for the treatment of BPH. Saw palmetto is an herbal product obtained from the fruit of the *Serenoa repens* tree with antiandrogen activity. The active ingredients are phytosterols; β-sitosterol and β-sitosterol-3-*O*-glucosides are the most abundant. Several trials have shown that it significantly improves BPH symptoms to a degree similar to that of finasteride.[61,87–90] However, a 2012 meta-analysis of 32 randomized trials failed to detect a difference in urinary symptom improvement even with triple the usual dose of saw palmetto compared to placebo.[91] The dose most often studied is 320 mg a day in one or two divided doses. Pygeum (*Pygeum africanum* bark extract) has been observed to moderately reduce urinary symptoms associated with enlargement of the prostate gland at a dose of 75 to 200 mg/day.[92] Pygeum has been well tolerated in most studies; however, the safety has not been extensively or systematically

studied. Herbal products may be tried by males with mild symptoms that would usually be managed by watchful waiting; however, the use of complementary and alternative medicines for BPH is not currently recommended by the AUA guidelines.[93]

Nonpharmacologic Treatment

TRANSURETHRAL RESECTION OF THE PROSTATE

Case 109-3, Question 7: What are the options if drug therapy does not work for G.M.? When should prostate surgery be undertaken in general?

G.M.'s subjective and objective findings, particularly the acute urinary retention and hydronephrosis, collectively indicate the need for a TURP. G.M. has been advised by his urologist that a TURP is the treatment of choice given the severity of his presentation (eg, large prostate gland with acute urinary retention) and that the procedure will relieve his symptoms, allow him to lead a relatively normal life, and avoid sequelae of prolonged obstruction.

TURP provides significant relief of BPH symptoms in 86%, 83%, 75%, and 75% of patients at 3 months, 1 year, 3 years, and 7 years, respectively.[94] Of patients with severe BPH, 93% report reduced symptoms 1 year after a TURP.[95] The TURP is considered the gold standard for the treatment of BPH and is used in 90% of patients with symptoms of residual urine or acute urinary retention. As a result, surgical alternatives are always compared with the outcome studies of TURP.

The need for a TURP in G.M.'s situation is fairly clear. In most cases, however, the need for a TURP is less clear because the symptoms do not inevitably worsen, and males often are willing to live with their symptoms. Therefore, clinicians need to talk with patients and help them answer the question of whether the discomfort, risk, and problems during the postsurgical recovery period are outweighed by the high probability that surgery will relieve symptoms.

SEXUAL DYSFUNCTION

As individuals are living longer, there is a growing interest in maintaining sexual health throughout later life. Nearly 39% of males and 17% of females between ages 75 and 85 reported being sexually active in a cross-sectional study published in 2010.[96] A nationally representative study concluded that most older adults are engaged in sexual activity and regard sex as an important part of life.[97] Poor health often is cited by older females as a reason for not participating in sexual activity, and among males, ED is the leading cause of decline in activity.[98],[99] The major factors that correlate with reduced sexual activity include an older spouse, poor mental or physical health, marital difficulties, previous negative sexual experiences, and negative attitudes toward sexuality in the aged.[100]

Male Sexual Dysfunction

In males, sexual function is considered an interaction between motivation, drive, desires, thoughts, fantasies, pleasures, experiences (referred to as the *libido*), penile vasocongestion, erection, orgasmic contractions, and ejaculations (referred to as *potency*).[101],[102] Testosterone plays an important role in male libido and sexual behavior and may play some role in penile erection. Older males show a strong correlation between advancing age and diminishing bioavailable serum testosterone levels.[103] Testosterone progressively declines after the seventh decade, partly because of testicular and hypothalamic–pituitary dysfunction.[104] Male sexual dysfunction, denoting the inability to achieve a satisfactory sexual relationship, may involve inadequacy of erection or problems with emission, ejaculation, or orgasm.

ED, also referred to as impotence, is defined by the National Institutes of Health Consensus Development Panel on Impotence and the Fourth International Consultation on Sexual Medicine as persistent or recurrent failure to achieve or maintain a penile erection to allow for satisfactory sexual intercourse.[105] Males may develop

different types of sexual dysfunction that have different underlying pathophysiology and require alternative treatment modalities. That males who have decreased libido have decreased sexual drive or desire and vice versa is true for those with increased libido. *Premature ejaculation* refers to uncontrolled ejaculation before or shortly after entering the vagina. *Retarded ejaculation* usually is synonymous with delayed ejaculation. *Retrograde ejaculation* denotes backflow of semen into the bladder during ejaculation caused by an incompetent bladder neck mechanism.

The Massachusetts Male Aging Study (MMAS) reported that in males ages 40 to 70 years, the overall prevalence of any degree of ED was 52%, and as high as 80% in those older than 70 years. There was an age-related increase in prevalence ranging from 12.4 cases per 1000 males per year in males ages 40 to 49 years, up to 46.4 cases per 1000 males per year in males ages 60 to 69 years.[106] Despite high prevalence, another study found that many patients do not seek treatment for ED and a possible reason could be reduced sexual activity in males ages 57 to 85 years.[107,108]

Contrary to the historical perception of ED as a symptom of the aging process, it is now well known that it is caused by a variety of medical, psychological, and lifestyle factors. Medical conditions such as HTN, arteriosclerosis, hyperlipidemia, diabetes mellitus, metabolic syndrome, or psychiatric disorders are associated with the development of ED. Medications used for the management of common chronic diseases may also exacerbate or lead to the development of ED. Approximately 80% of all cases of ED now are thought to be related to organic disease and subject to numerous influences.[109–112] In one study, neurologic and vascular disorders were the primary causes of ED among older adult males, and psychogenic factors were the cause in <10%.[103] The single most common etiology for erectile failure in older adults is severe atherosclerosis (eg, vascular disease and diabetes mellitus).[103] Cardiovascular disease, HTN, diabetes mellitus, elevated low-density lipoprotein cholesterol, and cigarette smoking are associated with a greater probability of complete ED in males.[113] Therefore, prevention of cardiovascular disorders by interventions such as low-

fat and low-cholesterol diets and abstinence from tobacco should minimize the development of ED.

Because ED is more likely in male patients with coronary artery disease, the understanding of the cardiovascular stresses involved with sexual intercourse can aid in patient management. Cardiac and metabolic expenditures during sexual intercourse vary depending on the type of sexual activity. Healthy males with their usual female partners generally achieve a peak heart rate of 110 beats/minute with female-on-top coitus and an average peak heart rate of 127 beats/minute with male-on-top coitus.[114] There is significant individual variation in cardiovascular response, when measured as oxygen uptake and metabolic expenditures, for male-on-top coitus.

In a study of patients with coronary artery disease who were medication free and in the New York Heart Association functional class I or II, sexual activity was compared with near-maximal exercise treadmill test.[115] Electrocardiographic changes representing ischemia during intercourse were found in one-third of the patients; however, two-thirds of these patients remained asymptomatic. All patients with ischemia during coitus also demonstrated ischemia during exercise treadmill testing. The average heart rate during coitus was 118 beats/minute, with some patients attaining a heart rate of 185 beats/minute at orgasm. Intercourse in patients with coronary artery disease may provoke increased ventricular ectopic activity that is not necessarily elicited by other stimuli.[116] These electrocardiographic changes and associated symptoms can be abolished with the use of β-blockers.[117] Sexual activity is a likely contributor to the onset of myocardial infarction only 0.9% of the time.[118] Coital death is rare, accounting for 0.6% of sudden death cases.[119] The hemodynamic changes associated with sexual activity may be far greater with an unfamiliar partner, in unfamiliar settings, and after excessive eating and alcohol consumption.

Erectile Dysfunction

NORMAL PENILE ERECTION PHYSIOLOGY

A harmony of several systems and factors is necessary for a normal, sustainable penile erection. Erection involves the neurologic, psychological, hormonal, arterial, and venous systems. Psychological stimuli are essential along with sexual stimuli to produce an erection.[120] The penis has two corpora made up of sinusoids that fill with arterial blood flow during an erection. The erection is prolonged by compression of subtunic venules, resulting in reduced venous outflow from the corpora. Arterial flow into the corpora is enhanced by neurotransmitters including acetylcholine, cyclic guanosine monophosphate (cGMP), and cyclic adenosine monophosphate (cAMP). On the other hand, norepinephrine decreases arterial inflow and increases venous outflow, which results in the progression of an erect penis to a flaccid state. The CNS plays a role in mediating erection through sensory sexual stimulation by sending nerve impulses from the spinal cord to peripheral cholinergic nerves that innervate the vascular supply to the corpora. The role of testosterone is complicated, yet important in stimulating libido and producing penile erection. Testosterone plays a role by targeting androgen receptors in penile endothelium and enhancing vascular process essential for penile erection.[120],[121] Declining serum testosterone levels, referred to as hypogonadism, have been associated with decreased libido, ED, and loss of spontaneous morning erections.[122] However, patients with normal testosterone levels can develop ED, and patients with low serum testosterone levels may remain asymptomatic and maintain normal sexual function. Owing to such variability, the FDA recommends treatment when serum testosterone levels are <300 ng/dL (10.4 nmol/L) and the patient has symptoms or signs of hypogonadism.[123] The European Association of Urology and the American Society of Andrology similarly recommend (a) no treatment if testosterone is >350 ng/dL (12.2 nmol/L), (b) treat if the patient has a serum testosterone of 230 to 350 ng/dL (8.0–12.2 nmol/L) and is symptomatic, and (c) treat if serum testosterone is <230 ng/dL (8.0 nmol/L).[124]

Evidence indicates that >80% of the cases of ED are because of organic causes, of which vascular disease is the most common.[125] In

most older male sexual dysfunction studies, 50% involve vascular problems and 30% relate to diabetes mellitus.[126]

Neurogenic disorders

ED can be caused by damage to the brain, spinal cord, cavernous or pudendal nerves, terminal nerve endings, and the receptors. Approximately 95% of patients with upper motor neuron lesions resulting from spinal injury are capable of erection through the reflexogenic mechanism, whereas only 25% of patients with complete lower motor neuron lesions can have erections through the psychogenic mechanism.[127] With incomplete lesions, up to 90% of patients in both groups retain erectile ability. Patients who have a cerebrovascular accident, dementia, epilepsy, Parkinson disease, or a brain tumor most likely experience erectile failure through loss of sexual interest or excessive inhibition of the spinal erection centers.[128]

Endocrine disorders

The incidence of ED with a hormonal cause has been estimated to be 5% to 35%, depending on which medical specialty is reporting the finding.[129] The most common hormonal disorder associated with ED in older adult is diabetes mellitus. Depending on the severity and duration of diabetes, the prevalence of ED ranges from 20% to 85%.[130]

Other endocrine disorders, such as hypothyroidism, hyperthyroidism, Addison disease, and Cushing syndrome, are associated with ED. Patients with hypogonadism caused by pituitary or hypothalamic tumors, antiandrogen therapy, or orchiectomy experience ED. These patients can have a normal erection from visual stimulation, however, indicating that the erectile mechanism is intact.[131]

Vascular disorders

Atherosclerosis is the leading vascular disease associated with male ED. The age of onset of coronary artery disease parallels the onset of ED, indicating a generalized atherosclerotic etiology for the ED.[132] The degree of arteriolar narrowing and clinical presentation, however, differs from patient to patient. Some patients can have severe coronary artery disease but retain the capability of a full erection. As long as the arterial flow into the penis exceeds the venous outflow, the patient can be potent. Narrowing of the arterial lumen lowers the pressure in the cavernous arteries, and poor arterial flow can only partially fill the sinusoidal system. Overall, the partial filling of the sinusoidal system causes inadequate expansion of the sinusoidal wall, resulting in partial compression of the venules. The net effect is a partial erection, difficulty in maintaining an erection, or early detumescence.

SIGNS AND SYMPTOMS

CASE 109-4

QUESTION 1: F.M., a 66-year-old male, was referred to a urologist because he was experiencing a loss of interest in sexual activity. He describes the inability to maintain a firm erection for the past 6 months in >75% of sexual attempts with his sexual partner. Physical examination was unremarkable except for an enlarged prostate gland and evidence of pubic and axillary hair loss. Vital signs were as follows:

Blood pressure, 160/95 mm Hg
Pulse, 88 beats/minute
Respirations, 14 breaths/minute
Temperature, 98.7 °F (37.06 °C)

Current medications include ramipril 5 mg once a day and glipizide 5 mg once daily. F.M.'s medical history is positive for cigarette smoking, HTN, and diabetes mellitus. Significant laboratory results include the following:

Hemoglobin A_{1c}: 7.2%
SCr, 1.5 mg/dL
BUN, 22 mg/dL
Free testosterone level, 30 pg/mL (normal, 52–280 pg/mL)
Luteinizing hormone (LH), 4 mU/mL (normal, 1–8 mU/mL)
Follicle-stimulating hormone (FSH) level, 40 mIU/mL (normal, 4–25 mIU/mL)

Serum prolactin level, 28 ng/mL (normal, >20 ng/mL)

What signs and symptoms does F.M. have that would suggest the need for a complete medical workup for ED?

F.M. presents with a loss of interest in sexual activity and the inability to maintain a full erection during >75% of sexual encounters with his partner. On physical examination, F.M. is found to have a noticeable loss of pubic and axillary body hair. With long-standing androgen deficiency, there may be loss of hair in the androgen-dependent areas of the body, fine wrinkling of the skin around the mouth and eyes, noticeable loss of muscle mass and strength, altered body fat distribution, and osteoporosis. In contrast, overt hypogonadism results in a change in the pattern of pubic hair from the male diamond shape to the female-inverted triangle appearance. At this point, it appears that F.M.'s loss of pubic and axillary hair is the result of androgen deficiency, with the cause yet to be determined. The laboratory results for gonadal function coincide with what is expected in an older male with ED (see Case 109-4, Question 4).

UROLOGIC WORKUP

CASE 109-4, QUESTION 2: What clinical evaluations and laboratory tests should be included in the medical workup of F.M. to determine the cause of his ED?

A detailed medical and sexual history and thorough physical examination are essential in the evaluation of sexual dysfunction. General medical history and physical examination should also consider drug-induced ED (**Table 109-12**).[133–150]

Table 109-12
Common Drug-Induced Alterations in Sexual Response

Drug Categories	Clinical Considerations
Antihypertensives	

Drug Categories	Clinical Considerations
Diuretic thiazides	Temporal association with sexual dysfunction. Reported incidence varies between 0% and 32%[133–136]; however, impotence generally is not considered common. Mechanism believed to be a “steal syndrome,” whereby blood is routed from erectile tissues to skeletal muscle[137]
Spironolactone	Associated with ↓ libido, impotence, and gynecomastia. Mechanism may be hormone related. Incidence is dose related and reported to be 5%–67%[137] and much more commonly encountered than with thiazides. May be owing to antiandrogen effects of drug
Sympatholytics	
Methyldopa	Central action mediated, causing vasodilation resulting in erectile dysfunction. Reported incidence: 10%.[137] Also ↓ libido
Clonidine	Induces erectile dysfunction. Mechanism similar to methyldopa and other central α_2-agonists. Incidence reported to be 4%–70% and dose related.[138—140] Also ↓ libido
Guanabenz, guanfacine	Incidence and mechanism believed to be similar to other central α_2-agonists
Nonselective β-Blockers	
Propranolol	Associated with erectile dysfunction and ↓ libido. Mechanism believed to be caused by ↓ vascular resistance and central effects. Erectile dysfunction reported to begin at doses of 120 mg/day. Incidence may be as high as 100% at higher dosages.[141,142]
Selective β-Blockers	
Atenolol, metoprolol, pindolol, timolol	Incidence of erectile dysfunction is significantly less than that of nonselective β-blockers.[143]
α-Blockers	
Doxazosin, prazosin, terazosin	Associated with erectile dysfunction and priapism.[139] Reported incidence: 0.6%–4%. Mechanism is local α_1-blockade resulting in vasodilation. Erectile dysfunction and priapism appear to be unique to the nonspecific α_1-antagonists.

Drug Categories	Clinical Considerations
Phenoxybenzamine	Associated with priapism, retrograde ejaculation, and inhibited emissions during erection. Effects are dose related.[144],[145]
Direct Vasodilators	
Hydralazine	Associated with erectile dysfunction. Mechanism is vascular smooth muscle relaxation. Incidence not reported[144]
Calcium Channel Blockers	
Amlodipine	Associated with erectile dysfunction. Mechanism believed to be vasodilation and, possibly, muscle relaxation. Reported incidence: <2%[146]
Diltiazem, verapamil	Similar to amlodipine. Reported incidence: <1%
Antiarrhythmics	
Class 1A disopyramide	Associated with erectile dysfunction in patients treated for ventricular arrhythmias. Incidence not reported. Mechanism believed to be caused by strong anticholinergic effect[144]
Anticonvulsants	
Carbamazepine, phenytoin	May be associated with sexual dysfunction through decreasing DHEA, which is a precursor to testosterone, estrogen, and pheromones
Antidepressants	
Selective serotonin reuptake inhibitors	Drugs with prominent serotonin agonist effects commonly cause delayed ejaculation and anorgasmia. The reported incidence for delayed ejaculation among males is 2%–12%; for anorgasmia among female users, the incidence appears to be >3%. This adverse effect is directly dose related.
Tricyclic antidepressants, monoamine oxidase inhibitors	Associated with impairment of sexual performance in both males and females: ↓ libido, anorgasmia, retrograde ejaculation, erectile dysfunction. Mechanism believed to be caused by anticholinergic and serotonergic effects. Incidence not reported; several case studies in the literature[137] (Note: The literature reports that, overall, there is less sexual dysfunction with desipramine than with other antidepressants.)

Drug Categories	Clinical Considerations
Trazodone	Associated with priapism in males and ↑ libido in females. Mechanism similar to TCA. Incidence not reported but believed to be dose related[137]
Antipsychotics	
Phenothiazines	Frequently associated with sexual dysfunction. Commonly, ↓ libido is reported. Mechanism is owing to hyperprolactinemia secondary to central dopamine antagonism. Erectile and ejaculatory pain is very common with this drug class; the α-antagonism and anticholinergic effects are responsible. Priapism is common with this drug group, owing to the peripheral α-blockade property. Incidence for all sexual dysfunctions with this drug class: ~50% of users[137]
Anxiolytics	
Short-acting barbiturates	Biphasic effect. At low doses, libido ↑, similar to ethanol, and at higher doses, CNS depression causes ↓ libido and performance.[137]
Benzodiazepines	Biphasic effect. At low doses, ↑ libido, whereas at higher dosages, CNS depression causes performance failure. Some reports of anorgasmia (males and females) and ejaculatory failure[137]
Substances of Abuse	
Alcohol	Alcohol is thought to impair sexual function through its chronic effects on the nervous system. Short-term use of alcohol can induce erectile dysfunction through its sedative effects. More than 600 mL/week of alcohol increases the probability of erectile dysfunction.[147] At low doses, it actually may enhance libido. Sexual dysfunction is dose related and caused by CNS depressant effects.[137]
Cocaine	Biphasic effect. At low doses, there is enhanced sexual desire (similar to amphetamines) and, possibly, performance. At higher dosages, there may be arousal dysfunction, ejaculatory dysfunction, and anorgasmia. Freebasing has been associated with spontaneous orgasm. Continued use (on a run) causes significant loss of sexual interest and performance ability. Chronic use associated with hyperprolactinemia resulting in ↓ libido[137]

Drug Categories	Clinical Considerations
Hallucinogens	Biphasic effect for most drugs in this category. At low doses, libido is enhanced; at higher doses, libido is severely ↓. No reports on chronic use[137]
Marijuana	Biphasic effect similar to ethanol. With chronic use, there is a ↓ in libido. Mechanism may be owing to ↓ testosterone. Incidence not reported[137]
Opioids	Associated with sexual dysfunction: erection lubrication, orgasm, and ejaculation. Chronic use associated with ↓ libido. Mechanism may be owing to α-antagonism, alterations in testosterone, and the intoxicating effects. Incidence not reported[148],[149]
Miscellaneous	
Amyl nitrate	Associated with intense and prolonged orgasms in both males and females. Impotence has been reported in some cases owing to vasodilation.[137]
Cimetidine	Associated with ↓ libido and erectile dysfunction. Mechanism owing to antiandrogen qualities and drug-induced elevation of prolactin. May be dose related.[150]
Metoclopramide	Associated with ↓ libido and erectile dysfunction. Mechanism is through CNS dopamine antagonism, resulting in hyperprolactinemia. Incidence not reported

CNS, central nervous system; DHEA, dehydroepiandrosterone; TCA, tricyclic antidepressants.

Although laboratory-based diagnostic procedures are available, sexual function may be best assessed in a naturalistic setting with patient self-report techniques. A psychometrically sound self-reporting tool is the International Index of Erectile Function (IIEF), which addresses the relevant domains of male sexual function (erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction) and has been linguistically validated in 10 languages.[151] A simplified version, the IIEF-5, is a five-item questionnaire that is also popular.[152]

F.M.'s endocrine status should include an assessment of his diabetes, thyroid function tests, and a serum lipid profile. Neuropathy and atherosclerosis are common findings among male patients with diabetes mellitus, and both are potential causes of ED. Patients experiencing hypothyroidism may have decreased libido, and hypothyroidism is associated with hyperprolactinemia, which can result in an inhibition in the release of testosterone. Elevated serum lipids (eg, total cholesterol, triglycerides) may be associated with significant vascular damage that could contribute to ED. Diabetes mellitus is best evaluated with hemoglobin A_{1c} and fasting blood glucose tests.[153]

The serum concentrations of free testosterone, prolactin, and LH should be evaluated. Testosterone, as with all other hormones secreted into the plasma, is available to tissues only in the free form (ie, unbound to serum proteins, particularly the sex hormone–binding globulin). Only 1% to 2% of testosterone is free and physiologically active; therefore, measurement of the unbound serum testosterone provides the best estimate of biologically available testosterone. Low testosterone serum concentrations are associated with primary and

secondary hypogonadism. Primary hypogonadism is associated with testicular disease (eg, Leydig cell tumors), whereas secondary hypogonadism is the result of pituitary or hypothalamic disease.

The serum prolactin concentration should be determined because a high serum concentration of prolactin inhibits the release of testosterone from the testes. Therefore, a low serum testosterone concentration may be caused by hyperprolactinemia. Hyperprolactinemia may be caused by prolactin adenomas, diabetes mellitus, or drug therapy (eg, neuroleptics, metoclopramide).

LH stimulates testicular steroidogenesis and secretion of testosterone. LH increases the conversion of cholesterol to pregnenolone, a precursor of testosterone. FSH is required for spermatogenesis in early puberty but is not a required gonadotropin for the maintenance of spermatogenesis in adult males. Normal testicular function depends on stimulation by the gonadotropin LH, which is secreted by the anterior pituitary gland. Consequently, a low normal serum concentration of LH is associated with secondary hypogonadism.

In patients with symptoms of prostatic disease, expressed prostatic secretions (EPSs) should be examined because prostate inflammation has been associated with ejaculatory dysfunction. During prostatic inflammation, the EPS contains leukocytes and macrophages, and microscopic examination of the EPS can determine the degree of prostate inflammation. The presence of >20 white blood cells per high-powered field in the EPS is abnormal and indicative of prostatitis. Only about 5% of prostatitis can be attributed to a bacterial infection; the remaining 95% is caused by unknown etiologies.

Ideally, assessment of ED should include urologic, endocrinologic, psychiatric, and neurologic evaluations as close together as possible. The signs and symptoms of ED must be identified carefully and described because medical intervention is indicated if it occurs for a 6-month period and in >50% of attempts.[111] A detailed history should determine whether ED varies with partners, sexual settings, position, and masturbation, and whether morning and nocturnal erections are impaired.

RELATIONSHIP OF MEDICAL HISTORY AND ERECTILE DYSFUNCTION

CASE 109-4, QUESTION 3: What is the relationship among HTN, cigarette smoking, diabetes mellitus, and F.M.'s ED?

Hypertension

In the MMAS, heart disease with HTN and low serum high-density lipoprotein correlated with ED.[110] The hemodynamics of erection can be impaired in patients with myocardial infarction, coronary artery bypass surgery, cerebrovascular accidents, and peripheral vascular disease.[153–157] In several studies of impotent males, the number of abnormal penile vascular findings significantly increased when the history included HTN and cigarette smoking. Control of blood pressure among hypertensive male patients does not necessarily improve erectile function, and antihypertensive medications can have a significant effect on ED and sexual performance (see Table 109-12).[158–160]

Cigarette smoking

The prevalence of cigarette smoking among males with ED is higher than that in the general population.[161–163] When the relation between cigarette smoking and erectile physiology was studied in 314 males with ED,[164] smoking was noted to further compromise penile physiology in males experiencing difficulty maintaining erections long enough for satisfactory intercourse. Several investigators report lower penile blood pressure indices, penile arterial insufficiency, and abnormal blood perfusion associated with cigarette smoking.[161],[165] Clearly, smoking cessation may benefit males with existing ED.

Diabetes mellitus

Diabetes mellitus has been associated with ED. In the MMAS, male patients with diabetes mellitus were three times more likely to have ED than were patients without diabetes.[109] Other investigators using

exclusively populations with diabetes have found a prevalence of ED as high as 75% among subjects.[166],[167] The onset of ED in the patient with diabetes occurs at an earlier age when compared with the general population. In a few cases, it may be the presenting symptom of diabetes mellitus, and, in most cases, ED follows within 10 years of the diagnosis, regardless of insulin dependence status.[168],[169] Researchers disagree as to the exact contribution of diabetes mellitus to ED, but most of the literature supports an atherosclerotic etiology.[170],[171] Other possible causes also include autonomic neuropathy and gonadal dysfunction.[170]

GONADAL FUNCTION IN ERECTILE DYSFUNCTION

CASE 109-4, QUESTION 4: What is the significance of the gonadal function results for F.M.?

Gonadotropins

Abnormalities of primary or secondary hypogonadism must be ruled out, particularly in patients with a decreased libido with or without ED. The results of F.M.'s gonadal function tests are relatively normal for an aged male. Testosterone serum levels decline with aging as a result of hypothalamic–pituitary changes or Leydig cell dysfunction. The understanding of changes that take place in the hypothalamic–pituitary level with advancing age is in a state of flux. For some time, most investigators focused on the increased serum concentration of male gonadotropins (LH, FSH), believing that all older males had some degree of primary hypogonadism.[172] Other studies have shown, however, that LH levels in older males are lower than the median of those in younger patients.[146] These findings show that LH levels do not increase in response to the decrease in testosterone serum concentrations in the aged male, indicating a defect in the hypothalamic–pituitary axis, leading to secondary hypogonadism.[173] Secondary hypogonadism results from dysregulation of pituitary LH release, resulting in low serum testosterone levels.[128]

Testicular size and aging

Testicular size decreases with age; however, the testicular degeneration is sporadic, thereby allowing most older males to maintain a normal or slightly decreased sperm output.[172] Overall, spermatogenesis decreases and is accompanied by an increase in serum concentration of FSH. FSH elevation correlates well with a decline in the number of Sertoli cells that secrete inhibin. Inhibin normally decreases FSH.[174]

Testosterone

As a result of primary or secondary hypogonadism in the older male, available testosterone declines. Approximately 60% to 75% of circulating serum testosterone is bound to a β-globulin known as sex hormone–binding globulin or testosterone-binding globulin. Approximately 20% to 40% of testosterone is bound to serum albumin, and 1% to 2% is unbound, or free. The unbound portion of the testosterone is the only active portion of the total serum testosterone concentration. Testosterone serum concentrations are 20% higher in the morning than in the evening, and this should be taken into consideration when evaluating laboratory results. In virtually all cases of ED, the serum concentration of testosterone should be measured in the morning.

Testosterone production is regulated by feedback from the hypothalamus and pituitary. The hypothalamus produces gonadotropin-releasing hormone (GnRH) in response to low testosterone levels. GnRH induces the pituitary to secrete LH and FSH, which in turn stimulates the Leydig cells of the testes to secrete testosterone. Less than 10% of cases of ED studied are caused strictly by hypogonadism.[103],[175] The role of testosterone in ED is complex. After testosterone production decreases, libido eventually declines and precedes the decrease in the frequency of erections.[176] Males given antiandrogens maintain their erectile capacity but have a decreased libido.[177] On the other hand, high dosages of androgens given to hypogonadal males increase both the frequency of erections and libido.[178] It would seem reasonable to postulate that at

physiologic levels, testosterone modulates the cognitive processes associated with sexual arousal more than it contributes to erectile capability.

Endocrine disorders

Many endocrine disorders can result in ED. Patients with prolactinomas commonly have ED, but prolactinomas account for <1% of ED cases.[141] Prolactin inhibits the release of testosterone, resulting in secondary hypogonadism. Hyperprolactinemia may be more prevalent in patients with diabetes.[179] In older adults, however, hyperprolactinemia often is secondary to the use of medications. F.M.'s serum prolactin level is elevated, most likely because of his diabetes mellitus.

In summary, aging males have a decrease in testosterone because of defects in testicular and hypothalamic–pituitary function. Secondary hypogonadism in older males is common, and the point at which this becomes pathologic has not yet been established. Correspondingly, the use of hormonal therapy to treat physiologic secondary hypogonadism is extremely controversial. Therefore, the gonadal function tests for F.M. are normal for his age and do not provide an explanation for his ED.

MEDICATIONS THAT CAUSE ERECTILE DYSFUNCTION

Case 109-4, Question 5: Is it likely that a medication is causing F.M.'s ED?

Several general statements can be made regarding sexual function and medications. Drugs that affect libido generally have a central mode of action. For example, medications that block central dopamine transmission can decrease libido, and opiates have an antiandrogen effect.[166] Drugs that alter hemodynamics may interfere with erection. Excessive sympathetic tone is thought to cause the "steal syndrome," which increases blood flow to muscles, drawing blood away from the erectile tissue.[155] Drugs that block the peripheral sympathetic system can cause retrograde ejaculation or

no ejaculation at all. Numerous drugs have been associated with altered sexual function (see Table 109-12).[180]

Most studies documenting drug-induced ED have been subjective and based on case reports, uncontrolled studies, and clinical impressions. The MMAS reported that ED was statistically correlated with antihypertensive, vasodilator, cardiac, and hypoglycemic drugs. The probability of moderate as well as complete ED was particularly high for vasodilator drugs.[101] Although the MMAS is one of the most well-designed studies to date, the medications reported are not considered to be the universe of all medications associated with ED. Diagnosis of drug-induced sexual dysfunction should be restricted to a reproducible dose-related effect that disappears on discontinuation of the drug.[113] A much larger survey of a controlled study in a clinical population would be required to establish any suspect medication as causative, rather than temporal.

F.M.'s sexual dysfunction (eg, loss of interest in sexual activity and ED) is not caused by his current drug regimen, ramipril and glipizide. Although the MMAS[101] reported a correlation between the use of antihypertensives and hypoglycemic drugs with ED, clinicians must look at the individual drugs themselves and the conditions for which they are prescribed. Sexual dysfunction is not likely to occur with ramipril, or any of the other angiotensin-converting enzyme inhibitors (ACEIs), or with the hypoglycemic agent glipizide. Although ramipril is an antihypertensive, its pharmacologic effects do not contribute to a decline in libido or cause ED (an advantage that ACEIs have compared with other antihypertensive medications). Similarly, the pharmacologic action of glipizide does not contribute to F.M.'s decreased libido or ED. In most sexual dysfunction cases, it is less likely that the medication is the direct cause of the problem; rather, it is the medical condition for which the drugs were prescribed. The ability of a drug to induce sexual dysfunction simply is an extension of its pharmacologic actions. As a general rule, drugs that manipulate the sympathetic or the parasympathetic system, both centrally and peripherally, are associated with sexual dysfunction.

Case 109-4, Question 6: What factors most likely are contributing to F.M.'s ED?

F.M. is a patient with HTN and diabetes who smokes cigarettes. Those three factors are more likely to be the cause of F.M.'s sexual dysfunction than are his medications. Diabetes mellitus is the most common hormonal disorder associated with ED in older adults.[167] The continued loss of interest in sexual activity experienced by F.M. most likely is the result of having experienced ED during past and present sexual events.

F.M.'s subjective and objective findings are common among older males. His sexual dysfunction is caused by atherosclerosis and possible neuropathy secondary to diabetes mellitus. Because cigarette smoking is no doubt contributing to F.M.'s ED, cessation should be encouraged; some improvement can be expected.[137] There is no need to alter F.M.'s drug regimen.

MANAGEMENT

Case 109-4, Question 7: What are the primary therapeutic considerations for F.M.?

Essentially, there are three levels to the management of ED. Level 1 includes lifestyle and drug therapy modifications. Specifically, the patient should be instructed to modify smoking and alcohol use. The patient's drug regimen should be checked periodically to ensure that drugs associated with ED are not being prescribed. If necessary, psychosocial counseling should be provided. After careful consideration, oral medications for the management of ED should be instituted. If level 1 therapies have failed or are not acceptable to the patient, then level 2 therapy is instituted. These interventions include a vacuum constriction device to elicit an erection, intracavernosal injections, or transurethral inserts. Level 3 management involves the placement of a penile prosthesis.

PHARMACOTHERAPY

Any therapy directed at male sexual dysfunction must include the elimination of drugs causing adverse sexual effects. Drug therapy is directed primarily toward treatment of ED and includes hormonal therapy, bromocriptine, prostaglandin E_1, sildenafil, tadalafil, vardenafil, avanafil, and apomorphine.

Phosphodiesterase-5 inhibitors

CASE 109-4, QUESTION 8: Would PDE-5I therapy be appropriate for F.M.? What are its side effects and contraindications? Does it interact with other drugs?

F.M. has diabetes mellitus and atherosclerosis and, therefore, is a candidate for treatment with a PDE-5I.[181] These agents are orally active and selective inhibitors of cGMP-specific PDE-5, the predominant phosphodiesterase isoenzyme metabolizing cGMP in the corpus cavernosum. They facilitate an erection in response to sexual stimulation by enhancing the nitric oxide–induced relaxation of corpus cavernosal smooth muscle. The results of double-blind, placebo-controlled clinical trials in males with ED of various causes have demonstrated that PDE-5Is significantly improve erectile function and the rate of successful sexual intercourse, with therapeutic outcomes approaching those of normal males of the same age.[182–184]

F.M. should be counseled on the adverse effects of PDE-5Is. The vasodilating action of PDE-5Is affects both the arteries and the veins, so the most common side effects are headache and facial flushing.[185] PDE-5Is cause a small decrease in both systolic and diastolic blood pressures, but clinically significant hypotension is rare. Studies of PDE-5Is and nitrates taken together show much greater drops in blood pressure. For that reason, PDE-5Is are contraindicated in patients taking long-acting nitrates or short-acting nitrate-containing medications.[110] In phase II/III studies before FDA approval, >3700 patients received sildenafil and almost 2000

received placebo in double-blind and open-label studies. Approximately 25% of patients had HTN and were taking antihypertensive medications, and 17% were diabetic. In these studies, the incidence of serious cardiovascular adverse effects was similar in the double-blind sildenafil group, the double-blind placebo group, and the open-label group. Twenty-eight patients had experienced a myocardial infarction. When adjusted for patient-years of exposure, no significant differences were seen in the myocardial infarction rates between the sildenafil and the placebo group, and no deaths were attributed to sildenafil.[186],[187] In an analysis of 67 double-blind, placebo-controlled trials of sildenafil, the overall frequency of death was comparable between the patients treated with sildenafil (13 of 8691; 0.15%) and placebo group (7 of 6602; 0.11%).[188] Nevertheless, several deaths caused by myocardial infarction or arrhythmia have been associated with the use of sildenafil.[189] Deaths associated with sildenafil (and presumably other PDE-5Is) are most likely caused by the increased cardiac workload in patients with unstable angina.[190]

Transient visual anomalies (mostly blue-green color-tinged objects, increased sensitivity to light, and blurred vision) have been reported in patients taking PDE-5Is, especially at higher dosages. These visual effects appear to be related to the weaker inhibiting action of PDE-5Is on the enzyme phosphodiesterase-6, which regulates signal transduction pathways in the retinal photoreceptors. In patients with inherited disorders of retinal phosphodiesterase-6, such as retinitis pigmentosa, PDE-5Is should be administered with extreme caution. In 2005, the FDA recommended that all PDE-5Is include a precaution in their labeling regarding the risk of nonarteritic anterior ischemic optic neuropathy as a cause of decreased vision including permanent vision loss. There have been only a handful of reports of nonarteritic anterior ischemic optic neuropathy in postmarketing surveillance, and most patients had underlying risk factors.[191] Clinicians should advise patients to discontinue the use of all PDE-5Is and seek medical attention in the event of sudden vision loss in one or both eyes.

The vasodilator actions of nitrates are profoundly amplified with concomitant use of PDE-5Is. This interaction likely applies to all nitrates and nitric oxide donors, regardless of their predominant hemodynamic site of action. They also may potentiate the inhaled form of nitrate, such as amyl nitrite, and therefore are contraindicated in patients using this product. Dietary sources of nitrates, nitrites, and L-arginine (the substrate from which nitric oxide is synthesized) do not contribute to the circulating levels of nitric oxide in humans and, therefore, are unlikely to interact with PDE-5Is. The anesthetic agent, nitrous oxide, is eliminated unchanged from the body, mostly via the lungs, within minutes of inhalation. It does not form nitric oxide in the human body and does not itself activate guanylate cyclase. As such, no contraindication exists to its use after the administration of PDE-5Is. The concomitant use of nitrates and PDE-5Is is contraindicated, although some differences in the nitrate-free period do exist based on the pharmacokinetic profile of the PDE-5I. After 24 hours, the administration of nitrates can once again be considered in patients using vardenafil and sildenafil; however, this should be extended to 48 hours in patients using tadalafil and can be shortened to 12 hours with avanafil.

Case 109-4, Question 9: Which PDE-5I should be recommended for F.M.?

Sildenafil

The typical dose of sildenafil is 50 mg orally, taken 1 hour before sexual activity. However, it may be taken anywhere from 4 hours to 30 minutes before sexual activity. The maximal recommended dosing frequency is once per day. The following factors are associated with increased plasma levels of sildenafil: age older than 65 years (40% increase in area under the curve), hepatic impairment (eg, cirrhosis, 80% increase), severe renal impairment (creatinine clearance >30 mL/minute, 100% increase), and concomitant use of potent CYP3A4 inhibitors (eg, erythromycin, ketoconazole, itraconazole, 200% increase). Because higher plasma levels may

increase both the efficacy and the incidence of adverse events, a starting dose of 25 mg should be considered in these patients. The dose may be increased to 100 mg. Because F.M. is older than 65 years, he should be started on 25-mg tablets of sildenafil. The dose may be increased under strict supervision.

Sildenafil is metabolized by both the CYP2C9 and the CYP3A4 pathways. Thus, inhibitors of the CYP3A4 isoenzyme, such as erythromycin or cimetidine, may lead to competitive inhibition of its metabolism; however, CYP3A4 is a high-capacity pathway. The effects of erythromycin or cimetidine on the half-life and physiologic effects of sildenafil are not known, but clinicians should be warned about the potential interaction.

Inadequate physical sexual stimulation while using any of the PDE-5Is can lead to treatment failure. Adequate sexual stimulation is needed to trigger the events leading to erection.[192] PDE-5Is cannot initiate an erection; they can only assist in the process. Some patients may need several attempts at sexual stimulation before they are successful with intercourse.

Tadalafil

Similar to sildenafil, tadalafil is a selective inhibitor of PDE-5. Tadalafil has several times more affinity for PDE-5 than does sildenafil.[193] Tadalafil and vardenafil, however, have minimal or no effect on visual disturbance (impairment of blue-green color discrimination), which is a well-recognized side effect of sildenafil.[194] Tadalafil's extended half-life of 17.5 hours relative to sildenafil most likely precludes its use in patients with angina or HTN. Tadalafil is metabolized by the hepatic CYP3A4 isozyme. Food has no effect on the oral absorption of tadalafil in contrast to sildenafil (bioavailability decreased by 29%). Tadalafil may be advantageous in a subset of patients, based on its shorter onset of action (16 minutes) and 24-hour duration of action.[195] Specifically, patients with psychogenic or neurogenic ED and those with stable cardiovascular systems may prefer tadalafil because it offers the potential for multiple sessions of intercourse with a single daily dose.

Vardenafil

Vardenafil is the third FDA-approved oral PDE-5I for the treatment of ED. The warnings regarding the use of nitrates while taking vardenafil are similar to the warnings for sildenafil. Patients using vardenafil may experience headache, flushing, or rhinitis; the incidence of these side effects is dose related.[196] Vardenafil is metabolized by the hepatic CYP3A4 isozyme and has a reported half-life of 5 hours.[197] Thus, drugs known to inhibit the CYP3A4 isozyme have the potential to prolong its half-life. Vardenafil 10 mg does not impair the ability of patients with stable coronary artery disease to exercise at levels equivalent to or greater than that attained during sexual intercourse.[198]

Avanafil

Avanafil is a PDE-5I with enhanced PDE-5 selectivity that may translate to fewer side effects because of less selectivity for non–PDE-5 isoenzymes found in the heart, retina, and skeletal muscle. The starting dose is 50 mg and should be taken 30 minutes before sexual activity, whereas the 100- to 200-mg doses can be taken 15 minutes before. It has a half-life similar to that of sildenafil and vardenafil and is rapidly absorbed following administration. Side effects and contraindications for avanafil are similar to that of the other PDE-5Is.[199]

F.M. has HTN that most likely would be affected by tadalafil; therefore, extreme caution is advised. Perhaps, the shorter-acting sildenafil, vardenafil, or avanafil would be the PDE-5I drug of choice for F.M.

Testosterone

Case 109-4, Question 10: Should F.M. be treated with testosterone?

Primary hypogonadism with severely deficient serum levels of bioavailable testosterone is the only appropriate indication for the

use of androgen hormone therapy.[141] The goal of androgen replacement therapy is to restore potency and libido by maintaining normal serum levels of testosterone.[200] Testosterone has no benefit in the treatment of eugonadal or mildly hypogonadal older males and actually may enhance the growth of undiagnosed adenocarcinoma of the prostate or cause further ED.[110] In eugonadal males, testosterone enhances the rigidity of the erection, but does not change the penile circumference.[201] F.M. would not be a candidate for testosterone therapy.

Case 109-4, Question 11: Which type of patient would benefit from testosterone therapy?

Unless testosterone deficiency is severe (free testosterone serum levels <7–8 pg/mL), testosterone replacement therapy will not improve the success rate of intercourse.[202] Testosterone replacement in patients with primary hypogonadism generally restores libido and potency. In some patients with secondary hypogonadism caused by disorders of the hypothalamus or pituitary, GnRH analogs can be administered to differentiate between hypothalamic and pituitary abnormalities and to correct testosterone deficiency.[200] Libido and potency then are restored.

Case 109-4, Question 12: How should testosterone be used as a treatment for ED?

Testosterone replacement therapy is available in several formulations, including gels, transdermal patches, and intramuscular injection. Because of poor drug bioavailability, oral testosterone replacement therapy is less effective than is parenteral testosterone in achieving normal serum testosterone levels. Oral administration also is associated with a higher incidence of hepatotoxicity and adverse serum lipid effects.[110],[146] A long-acting testosterone intramuscular formulation, such as the enanthate or cypionate ester, is still considered the regimen of choice for the treatment of primary

hypogonadism. A dose of 50 to 400 mg should be administered intramuscularly every 2 to 4 weeks. Side effects of testosterone therapy include early gynecomastia, increases in hematocrit (sometimes to the point of polycythemia), and fluid retention that may worsen HTN or heart failure.

Results of several studies have demonstrated that serum testosterone levels are normalized while using transdermal testosterone applications.[147,203–205] The system normalizes DHT to testosterone ratios and reduces LH levels toward the normal range. The transdermal testosterone is well tolerated, with application site reactions such as pruritus, burn-like blisters, and erythema being the most commonly reported event. The adhesive side of the patch should be applied to a clean, dry area of the skin on the back, abdomen, upper arms, or thighs. The patient should be instructed to avoid application over bony prominences or on a part of the body that may be subject to prolonged pressure during sleep or sitting (eg, the deltoid region of the upper arm, the greater trochanter of the femur, and the ischial tuberosity); do not apply to the scrotum. The sites of application should be rotated, with an interval of 7 days between applications to the same site. The area selected should not be oily, damaged, or irritated.

Topical testosterone gel should be applied once daily in the morning to clean, dry skin. Depending on the specific product, it can be applied to the upper arms, shoulders, thighs, or abdomen. A topical solution for application to the axilla is also available. The dose can be as high as 100 mg/24 hours. After the gel or solution has dried on the site of application, it should be protected with clothing to prevent the transfer to a nonuser. The patient should wash their hands after application.

Commonly reported adverse effects in chronic users include acne, edema, gynecomastia, and dermatologic reactions to injections or transdermal applications of testosterone. The most serious risk of prolonged testosterone use is prostate carcinoma, although the association between high concentrations of testosterone and the risk of prostate carcinoma is controversial.[206–208] Three studies suggest that testosterone replacement therapy is relatively safe in

hypogonadism.[209–212] Baseline assessment of the prostate should be done before starting testosterone replacement therapy. This should consist of a TRUS, digital palpation of the prostate gland, and analysis of the PSA, hemoglobin, and hematocrit levels.

Bromocriptine

Case 109-4, Question 13: Because F.M.'s prolactin serum concentration is 28 ng/mL, should bromocriptine be prescribed to decrease his hyperprolactinemia and treat his ED?

Hyperprolactinemia may be treated with the ergot alkaloid bromocriptine, which works as a dopamine agonist to inhibit prolactin secretion. Even with normalization of prolactin levels, ~50% of older male patients are unable to achieve erectile function and desire.[146],[168] Bromocriptine therapy may be initiated with twice-daily 1.25-mg doses taken with meals to minimize GI upset. Thereafter, doses may be increased weekly, at a rate of no more than 2.5 mg/day. Adverse events associated with bromocriptine are nausea, dizziness, drowsiness, hypotension, and cerebrovascular accidents.[110],[168] For those who fail bromocriptine, cabergoline is a reasonable alternative given once or twice a week with good efficacy and a lower incidence of nausea.[212]

F.M. is not a candidate for treatment with bromocriptine because he does not have secondary hypogonadism, and his ED probably is secondary to atherosclerosis associated with his HTN, diabetes, and cigarette smoking. Furthermore, the elevation of F.M.'s serum prolactin concentration is not significant enough to warrant drug therapy. Medication-induced hyperprolactinemia is usually associated with prolactin levels ranging from 25 to 100 µg/L, but metoclopramide, risperidone, and phenothiazines can lead to prolactin levels exceeding 200 µg/L by way of dopamine antagonism.[212] Verapamil can cause hyperprolactinemia presumably by blocking hypothalamic dopamine, and opiates and cocaine can induce it through the µ-receptor.[212] Usually, prolactin will normalize 3

days following discontinuation of the offending medication; however, this patient is not on any medications that can induce hyperprolactinemia. Because the response rate to bromocriptine in older males is 50% (or less), the risk of adverse reactions (eg, dyskinesia, dizziness, hallucinations, dystonia, confusion, cerebrovascular accidents) outweighs the benefit of this dopamine agonist therapy.

CASE 109-4, QUESTION 14: What other drug therapy is available for F.M.?

Before the advent of the PDE-5Is, intracavernosal and intraurethral prostaglandin E_1 (alprostadil) administration was the only nonsurgical option for ED. Alprostadil causes direct vascular smooth muscle relaxation, allowing blood flow and entrapment in the penis. Less invasive than are intracavernosal injections, alprostadil intraurethral pellet is inserted, as a semisolid gel form, through the urethral opening of the penis 5 to 10 minutes before sex and works for up to 1 hour. However, it is less effective and not recommended for pregnant partners.[213] Intracavernosal injections are given at the base of the penis 10 to 20 minutes before sex and were effective in 87% of cases in one clinical trial.[214] Phentolamine, papaverine, and vasoactive intestinal peptide are also available for intracavernosal injection but are not FDA approved. Adverse events from intracavernosal therapies include priapism, pain at the injection site, and penile fibrosis after long-term use. Topical alprostadil cream has also shown efficacy in 74% of patients but is not currently available in the United States.[215]

Osteoporosis

Mary-Kathleen Grams, R. Rebecca Couris, and Suzanne Dinsmore

CORE PRINCIPLES		CHAPTER CASES
1	Osteoporosis is a condition of low bone mass and deterioration of bone tissue leading to bone fragility and potentially fracture with many preventable and inherent risk factors.	**Case 110-1 (Question 1)** **Case 110-4 (Question 1)**
2	Prevention and treatment of osteoporosis focus on modifying preventable risks, providing adequate dietary supplementation of calcium and vitamin D, increasing bone mineral density, and reducing fracture rates. A detailed medical history should be collected from each patient.	**Case 110-1 (Questions 1–3)** **Case 110-2 (Questions 1, 3)** **Case 110-3 (Question 1)**
3	Pharmacologic therapy is reserved for those patients with a hip or vertebral fracture, individuals with a T-score ≤ –	**Case 110-2 (Questions 2, 6)**

	2.5 at the femoral neck or spine once secondary causes have been excluded, and individuals with low bone mass with a 10-year probability of ≥3% risk of hip fracture or ≥20% risk of major osteoporotic fracture.	
4	Initial therapy with oral bisphosphonates is recommended unless patients are unable to take or have relative contraindications to oral bisphosphonate therapy.	**Case 110-3 (Question 2)**
5	Estrogen/progesterone therapy, selective estrogen-receptor modulators, parathyroid hormone analogs, denosumab, calcitonin, and romosozumab are alternative therapies for the prevention and/or treatment of postmenopausal osteoporosis.	**Case 110-2 (Questions 4, 5) Case 110-3 (Questions 3, 4) Case 110-4 (Questions 2–4)**
6	Duration of treatment with antiresorptive and/or anabolic therapy has remained controversial, secondary to concerns for oversuppression of bone turnover markers and the potential for the development of osteosarcomas, respectively.	**Case 110-3 (Question 2)**
7	Prevention and treatment of osteoporosis secondary to prolonged glucocorticoid therapy should be incorporated into a patient's treatment plan with considerations for dosage and duration of glucocorticoid therapy, the	**Case 110-5 (Questions 1–4)**

	patient's individual risk factors, sex, and age.	
8	Pharmacologic therapies to be considered for osteoporosis treatment in males include oral and intravenous bisphosphonates, denosumab, and parathyroid hormone.	**Case 110-6 (Questions 1–6)**

INTRODUCTION

Osteoporosis is a well-recognized disorder of reduced bone strength leading to an increased risk of fractures. It is the most common bone disease in humans, characterized by low bone mass and a deterioration of bone tissue.[1]

Osteoporosis is considered a silent disease and can progress without symptoms until a fracture occurs.[1] Fractures of the spine, hip, and wrist are the most common and may be followed by a complete recovery, varying degrees of pain and disability, and even death.[1] Osteoporotic fractures negatively impact physical, financial, and psychological health. Their complications lead to a heavy economic burden, considerable morbidity and mortality, making osteoporosis a major public health concern.[2]

The main causes of osteoporosis are loss of cell function because of natural aging, also known as senescence, and loss because of declining hormonal function.[3] Age-related bone loss begins in the third decade of life and is accelerated in females in the late peri-menopausal period and first postmenopausal years.[3],[4] Conditions that contribute to osteoporosis are prolonged periods of inadequate calcium intake, sedentary lifestyle, and tobacco and alcohol abuse. Deterioration of bone mass is also associated with chronic conditions or from the use of various medications.[5] Risk factors for osteoporosis are listed in **Table 110-1** and include nutritional deficiencies, endocrine disorders such as hyperparathyroidism and diabetes

mellitus, malignancies, gastrointestinal (GI) diseases, renal failure, connective tissue diseases, and medications, which include anticonvulsant therapy, long-term glucocorticoid therapy, or long-term proton pump inhibitors.

Table 110-1
Risk Factors Associated With the Development of Osteoporosis

↑Age Female gender Caucasian or Asian Family history Small stature Low weight	Predisposing medical problems (eg, chronic liver disease, chronic renal failure, hyperthyroidism, primary hyperparathyroidism, Cushing syndrome, diabetes mellitus, anorexia nervosa, gastrointestinal resection, malabsorption, vitamin D deficiency, irritable bowel disease, chronic obstructive pulmonary disease, spinal cord injury, Parkinson disease, and human immunodeficiency virus)
Early menopause or oophorectomy Sedentary lifestyle ↓Mobility Low calcium intake Excessive alcohol intake Cigarette smoking High caffeine intake	Drugs (eg, corticosteroids, long-term anticonvulsant therapy [phenytoin or phenobarbital], aromatase inhibitors, gonadotropin hormone–releasing hormone [GnRH] analogs, depot medroxyprogesterone, rosiglitazone, cyclosporine, tacrolimus, anti-retroviral therapy, long-term heparin, warfarin, loop diuretics, excessive levothyroxine therapy, proton pump inhibitors, H_2-receptor antagonists, excessive use of aluminum-containing antacids)

The standard method of identifying osteoporosis is the measurement of bone mineral density (BMD) at either the femoral neck region of the proximal femur (hip) or the lumbar spine.[2] The World Health Organization (WHO) uses a defined criteria to diagnose osteoporosis that has been widely accepted.[6] When measured by dual-energy x-ray absorptiometry (DEXA), a BMD that lies 2.5 standard deviations (SDs) or more below the average value for young, healthy females, a T-score of < −2.5 SD, is considered osteoporosis and an effective method to identify patients at

increased risk for fracture. As the T-score decreases, the risk for fracture increases. A T-score between −2.5 and −1 is defined as osteopenia but is better referred to as low bone mass or low bone density. A T-score ≥ −1 is considered normal. The National Osteoporosis Foundation (NOF) clinician guidelines includes this measurement of BMD in the diagnosis of osteoporosis but also states that the occurrence of adulthood hip or vertebral fracture in the absence of major trauma can be considered osteoporosis without the measurement of BMD.[1]

Although the fracture rate is lower than in osteoporosis, the majority of fractures occur in patients with low bone mass. The prevalence of low bone mass is higher than osteoporosis, and therefore it is important to monitor for clinical risk factors to predict the risk of fracture.

Osteoporosis is a global concern estimated to affect more than 200 million people worldwide.[7] The prevalence of osteoporosis and the risk of fracture increase with age and varies by race and ethnicity. The risk of hip fracture is greatest in Northern Europe, Australia, and North America.[8] According to data from the United States National Health and Nutrition Examination Survey (NHANES), 2005 to 2010 and the 2010 U.S. Census, it was estimated that 10.3% or 10.2 million adults ages 50 years and older had osteoporosis and 43.9% or 43.4 million adults had low bone mass.[9] Almost 80% of the affected population were females. Osteoporosis at either the femoral neck or lumbar spine ranged from 7% to 35% in females and 3% to 10% in males in the 5th through 8th decades of life. Prevalence increased with each decade after age 50 years in females, but not until age 70 years in males. The prevalence of low bone mass at either the femoral neck or lumbar spine in adults ages 50 years and over ranged from 54% to 67% in females and 32% to 60% in males in the 5th through 8th decades of life. The prevalence of low bone mass in females increased with age until age 70 years and then remained stable. In males, the prevalence of low bone mass did not increase with age until age 70 years and increased progressively thereafter.

The NHANES, 2013 to 2014, provides a separate estimate of osteoporosis and low bone mass by race and ethnicity in four different groups.[10] Overall prevalence of osteoporosis of either femoral neck or lumbar spine in adults ages 50 years and older was 11%, 16.5% females and 5.1% males. The age-adjusted prevalence of osteoporosis in females was highest in non-Hispanic Asians (40%), followed by Hispanics (20.5%), non-Hispanic Whites (17%), and lowest among non-Hispanic Blacks (8.2%). In males, the rate of osteoporosis was also highest among non-Hispanic Asians (7.5%), followed by non-Hispanic Whites (6%), Hispanics (5.9%), and non-Hispanic Blacks (1.9%). The age-adjusted prevalence of low bone mass in females was highest among the Hispanic race (57%) followed by non-Hispanic Whites (54.6%), non-Hispanic Asian (47%), and non-Hispanic Black (40.4%). In males, prevalence among race followed a different trend: non-Hispanic Asian (47.7%), Hispanic (38.1%), followed by non-Hispanic White (37.3%) and non-Hispanic Black (25.7%).

The clinical and economic consequences of osteoporosis are related to the impact of osteoporosis-related fractures. According to the International Osteoporosis Foundation (IOF), one of three females and one of five males over age 50 will experience fracture because of osteoporosis.[11] Approximately 50% of Caucasian females and 20% of males will sustain an osteoporosis-related fracture in their lifetime.[1] The risk of fracture is highest in Caucasian females, followed by Asian, African American, and Hispanic females.[8] More than 1.5 million fractures per year occur in the United States that are attributed to osteoporosis.[12] Estimated costs range from 14 to 20 billion dollars each year and include more than 432,000 hospital admissions, 180,000 nursing home admissions, and almost 2.5 million medical office visits.[1],[12] Hip fractures account for almost three-fourths of the total cost of osteoporosis-related care, yet represent only 14% of the incident fractures. Hip fractures have a profound impact on the quality of life and a considerable associated mortality. The mortality during the first year after hip fracture is as high as 36% with a higher mortality in males than females.[1] There is a 2.5-fold increased risk of future fractures relative to persons of the

same sex and similar age without fractures. In addition, hip fractures result in a multitude of complications for the elderly, including prolonged hospitalization, decreased independent living, depression, fear of future falls, and lifelong disability. An estimated 20% require long-term nursing home placement, and ~60% are unable to regain their prefracture level of independence. Vertebral fractures may be painless or result in pain that usually lasts <3 months. The initiating injury may be as minor as a cough or turning over in bed. After the first, the risk of additional vertebral fractures is high. Vertebral collapse or deformity can result in loss of height, kyphosis, abdominal protuberance or decreased pulmonary function as the abdominal cavity is shortened, chronic back pain, decreased mobility, or mortality.

The rates of osteoporosis and low bone mass have recently declined, but the total numbers of males and females with osteoporosis and low bone mass remain high.[9] The total number of 53.6 million adults over age 50 years with osteoporosis or low bone mass could potentially increase by 30% in the year 2030 based on the trends from 2005 to 2010. The impact of osteoporosis on the health care system, rising health care costs, in an aging population is potentially staggering.

Etiology

Bone is composed of bone cells (osteocytes, osteoblasts, osteoclasts), collagenous and noncollagenous protein, and minerals and innervated with blood vessels and nerve fibers.[13] Eighty percent of bone that makes up the adult human skeleton is cortical bone, a dense compact bone that surrounds the marrow space. Twenty percent is trabecular bone, which is less dense than cortical bone and often referred to as spongy or cancellous bone. Cortical bone forms the outer shell as a protector of the marrow space, and a network of trabecular bone forms the interior structures in the bone marrow compartment in a honeycomb-like fashion. Depending on

location, bone consists of varied ratios of cortical to trabecular bone leading to differences in hardness and porosity.

The bones of the skeleton help to support and protect the body and undergo cycles of modeling (reshaping) and remodeling (renewal) to remove older bone and to replace it with stronger newly formed bone.[13] Osteoclasts resorb old bone by increasing enzymes that dissolve bone proteins and minerals. Osteoblasts reform bony surfaces and fill bony cavities by synthesizing a bony matrix that is made up of type I collagen and other proteins. Osteoblasts become osteocytes as they are surrounded by the new bone matrix. Bone minerals deposit into the new bony matrix strengthening newly formed bone. In young healthy bone, a balance between osteoblast and osteoclast activity results in a continuous remodeling process. When the rate of resorption or removal exceeds the rate of replacement, the resulting bone loss decreases bone strength and increases the risk of fracture.

Bone mass peaks between ages 18 and 25 and begins to gradually decrease beginning at ~age 30.[3],[14] An age-related bone loss of 20% to 30% cortical bone and 20% to 30% of trabecular bone occurs in both males and females over a lifetime. Lifetime losses of vertebral bone, which is mainly trabecular bone, can approximate 45% in males and 55% in females.[3]

Bone loss is accelerated in females during the peri-menopausal and menopausal transition and after surgical oophorectomy.[3] A loss of 20% to 30% of trabecular bone and 5% to 10% of cortical bone is because of the decline in 17β-estradiol concentrations and results in an increased prevalence of osteoporosis in females and an increased fracture risk that can be seen early after menopause.[3],[15] Females are also at higher risk of osteoporosis as they tend to have smaller bones and less bone mass than males of similar age.

In males, androgens and estrogens play a role in the growth and development of bone.[3],[16],[17] Serum testosterone concentrations decline by approximately two-thirds over a lifetime. Aromatization converts testosterone to estrogen, and because of a decline in testosterone, available estrogen decreases by ~50% over the male life span. Testosterone has a direct beneficial effect on bone, but to a

lesser extent than estrogen. Decreases in bioavailable estrogen as well as cellular senescence contribute to bone loss and reduced BMD in older males.[3,17]

Other hormones regulated by the hypothalamic–pituitary– gonadal axis (eg, progesterone, follicle-stimulating hormone, inhibins, oxytocin, and prolactin) have been studied for their effects on the skeletal system.[18]

Pathophysiology

Bone remodeling occurs throughout life to maintain bone strength and calcium and phosphorus homeostasis and can replace up to 20% of the human skeleton each year.[19] It is a complex process that involves a balance of local and systemic regulators to form discrete skeletal foci or bone-remodeling units.[14] Osteoblasts and osteoclasts play a major role in remodeling, and there is a coupling of bone formation and resorption processes. Factors such as transforming growth factor-β (TGF-β), insulin-like growth factor (IGF), and cytokines signal the end of bone resorption and the beginning of bone formation.[13] The receptor activator of nuclear factor-μB ligand (RANKL) and osteoprotegerin (OPG) are also important local regulators that determine the formation, activation, and resorption of osteoclasts in remodeling.[13,20] RANKL and macrophage colony-stimulating factor (M-CSF) are required for differentiation of osteoclast precursors (**Fig. 110-1**).

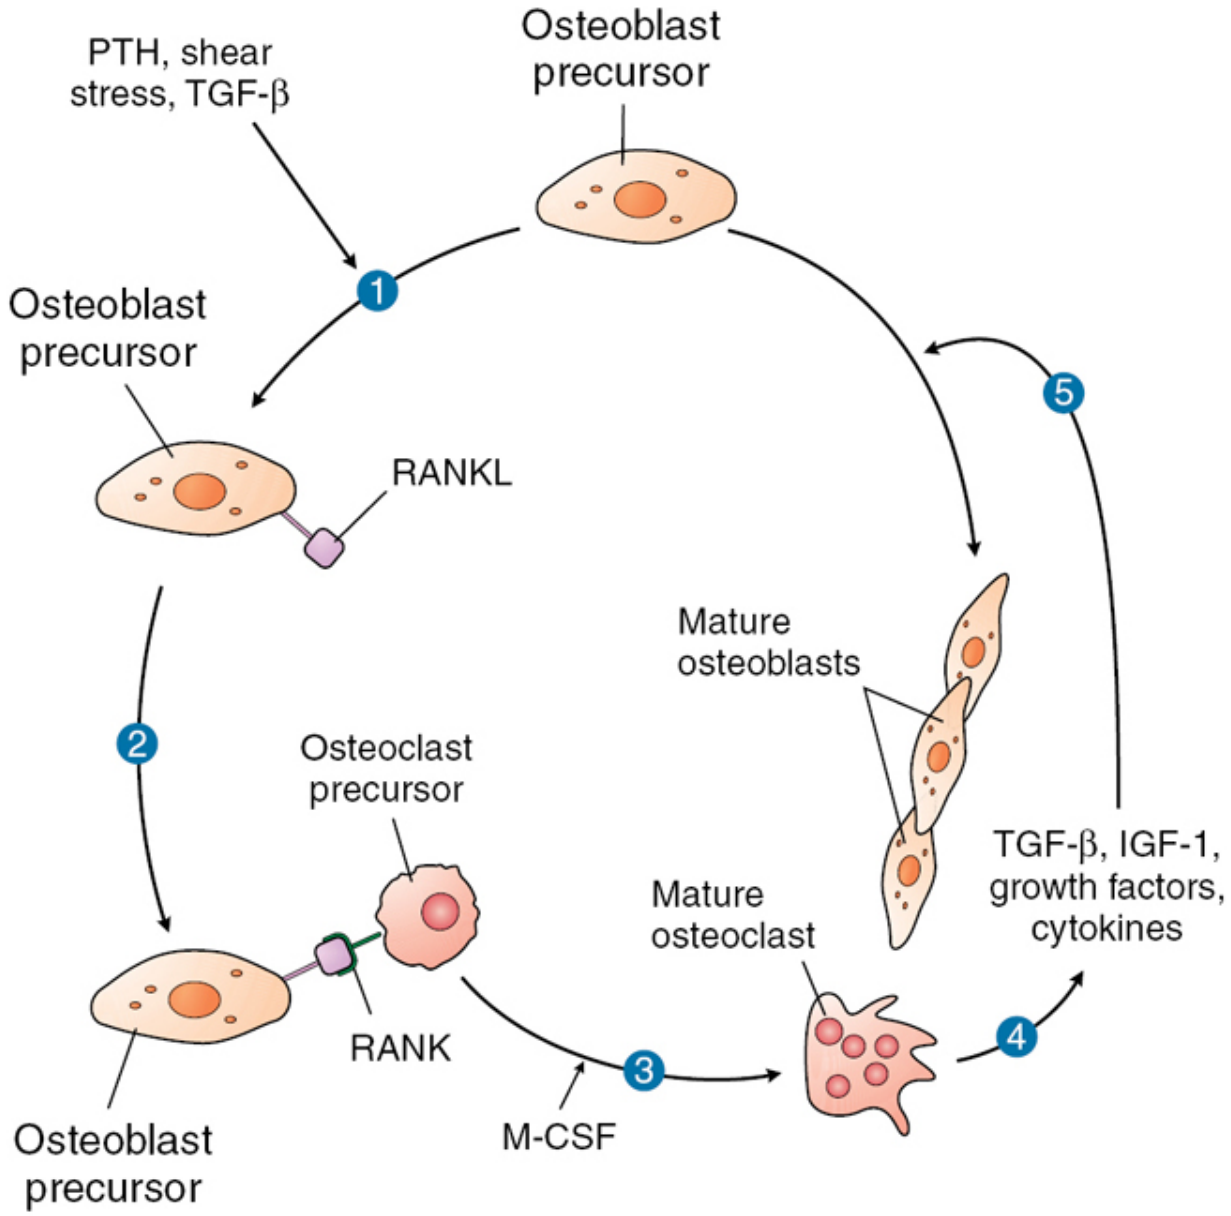

Figure 110-1 The bone-remodeling cycle at the cellular level. IGF, insulin-like growth factor; M-CSF, macrophage colony-stimulating factor; PTH, parathyroid hormone; RANKL; receptor activator of nuclear factor-μB ligand; TGF-β, transforming growth factor-β.

RANKL is expressed on osteoblasts and binds to the osteoclast RANK receptor to facilitate osteoclast differentiation and resorptive activity.[13,20] OPG is a decoy receptor preventing the interaction between RANKL and RANK receptor and inhibiting osteoclast

stimulation. The transition of bone resorption to bone formation is dependent on the RANKL/OPG ratio.

Local and systemic factors can influence bone homeostasis by modulating the RANKL/RANK/OPG system.[3],[21] Systemic modulators of bone remodeling include parathyroid hormone (PTH), vitamin D, glucocorticoid hormones, calcitonin, estrogen, and testosterone. PTH and glucocorticoid hormones have been associated with bone resorption, whereas calcitonin, estrogen, and testosterone have been associated with bone formation. Vitamin D is associated with both formation and resorption in response to serum calcium levels.[22]

PTH maintains calcium balance and regulates bone mass by both stimulating RANKL and inhibiting OPG.[21] Balance is closely regulated by the absorption of calcium in the GI tract and reabsorption by the kidneys. Serum calcium levels are primarily regulated by the actions of PTH, vitamin D, and calcitonin. The parathyroid gland releases PTH in response to low serum calcium levels, which in turn facilitates the mobilization of calcium and phosphate from bone through bone resorption and stimulates the reabsorption of calcium through the tubular system in the kidneys.[14] Vitamin D aids in intestinal absorption of calcium, phosphorus, and magnesium. Increases in vitamin D levels decrease PTH levels. Vitamin D also increases bone resorption to prevent symptomatic hypocalcemia (**Fig. 110-2**). Calcitonin is released in response to high serum calcium levels. Calcitonin decreases intestinal absorption of calcium and phosphorus, enhances calcium excretion in the kidneys, and prevents bone resorption.

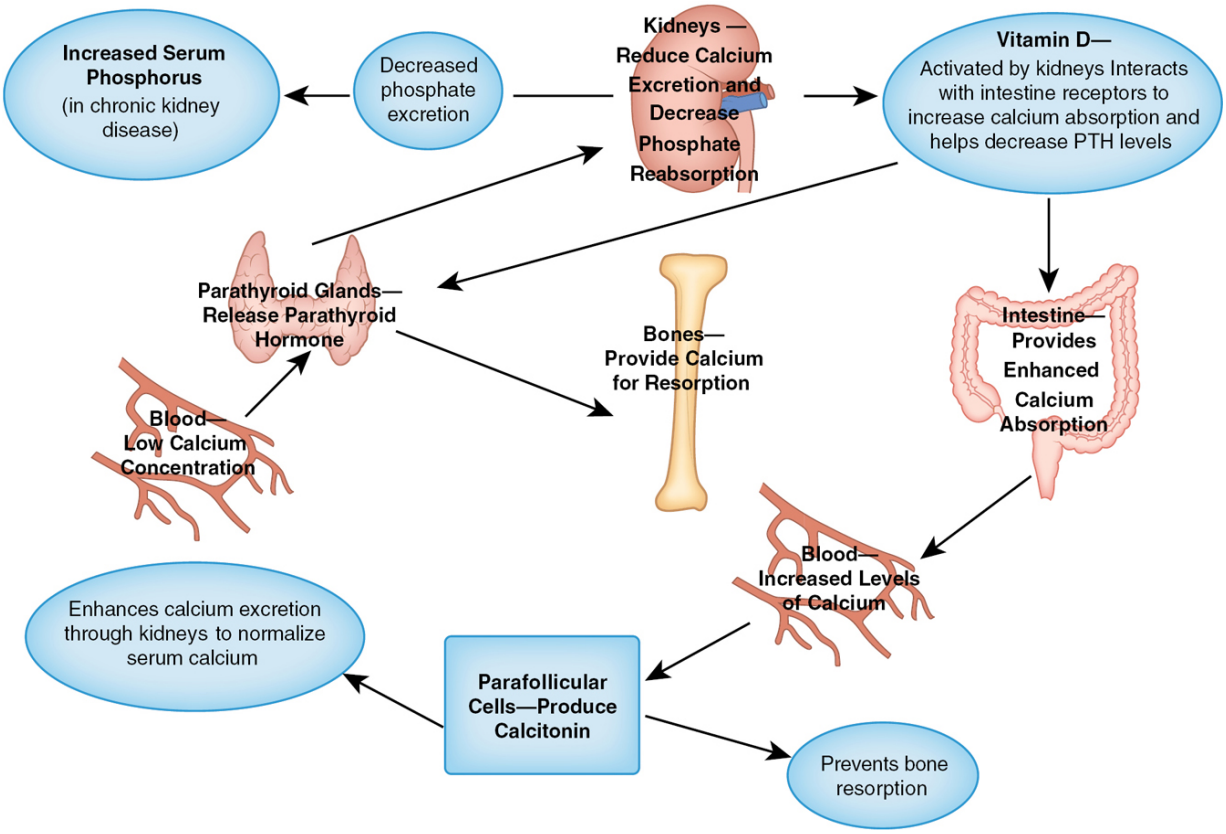

Figure 110-2 Pathway for calcium homeostasis with involvement from parathyroid hormone, vitamin D, and calcitonin.

Bone remodeling is also associated with multiple bone turnover markers.[19] Markers of bone formation include propeptides of type 1 collagen (P1CP, P1NP), alkaline phosphatase (ALP), and osteocalcin. Markers of bone resorption include markers such as collagenous and noncollagenous degradation proteins, cathepsin K, and sclerostin.

Systemic and local factors of remodeling and bone turnover are areas of research in the management of osteoporosis.

Overview of Drug Therapy

Osteoporosis is a condition of low bone mass and deterioration of bone tissue with a high risk for fracture. Prevention, identification, and treatment of osteoporosis should all be incorporated into primary health care. Preventive measures to reduce fracture risk include

adequate intake of daily calcium and vitamin D. Lifestyle modifications that are universally recommended are weight-bearing exercise, reduced alcohol consumption, and smoking cessation. Fall prevention strategies are also universal suggestions. These recommendations apply to both males and females. Pharmacologic treatment should be considered in patients with low trauma hip or vertebral fracture, patients with a T-score of < −2.5, and patients with low bone mass who are at increased risk for fracture. Medications include selective estrogen-receptor modulators (SERMs; eg, raloxifene) and calcitonin in females, bisphosphonates (eg, alendronate), RANKL inhibitors (eg, denosumab), anti-sclerostin agent (eg, romosozumab), and PTH analogs for both males and females.[23] Testosterone therapy is recommended for males at high risk for fracture with low testosterone levels (<200 ng/dL or 6.9 nmol/L) who cannot tolerate the approved pharmacologic agents for osteoporosis.[24]

Risk Factors

CASE 110-1

Question 1: T.J., a 28-year-old, thin Caucasian female, is worried about developing osteoporosis. Her 75-year-old maternal grandmother has osteoporosis, and recently her postmenopausal mother (age 53) was told that she was at increased risk for osteoporosis. T.J. is 62 inches (157.48 cm) tall, weighs 108 pounds (49 kg), and is in good health. She jogs and occasionally does aerobic exercise. Her diet typically consists of cereal for breakfast, a sandwich for lunch, and meat with vegetables for dinner. Her only milk consumption consists of 1 cup of skim milk on her cereal. She occasionally has a dairy product for lunch or dinner. T.J. takes no medications, vitamins, or calcium supplements routinely. She occasionally takes a medication for headache or menstrual cramps. She does not smoke and occasionally drinks alcohol.

Does T.J. have an increased risk for developing osteoporosis?

Table 110-1 lists risk factors associated with the development of osteoporosis. T.J. has several risk factors that could increase her risk

for osteoporosis. She is a White female of small stature and low weight (body mass index [BMI] = 19.8 kg/m^2), has a positive family history, and has a low calcium intake.

Prevalence of osteoporosis worldwide varies with gender, race, and ethnicity.[8] In the United States, non-Hispanic Asians have the highest risk of osteoporosis.[10] Non-Hispanic White females and Hispanic females have an intermediate risk of osteoporosis but a significantly higher risk of low bone mass.

LOW BODY MASS INDEX

T.J. has a small stature, and a BMI just under 20 kg/m^2 and on the low side of normal (range 18.5–24.99 kg/m^2). Low BMI (<20) is an established independent risk factor for osteoporosis and increases the risk of fracture.[23],[25] In a meta-analysis of 12 cohorts including 60,000 males and females, a BMI of 20 kg/m^2 was associated with almost twice the risk of hip fracture compared to a BMI of 25 kg/m^2.[26] A BMI of 30 kg/m^2 was associated with a 17% reduction in the risk of hip fracture compared to 25 kg/m^2. Nevertheless, obesity should not be considered a protective factor. When adjusted for BMD, there was still a 42% increase in hip fracture in patients with a BMI of 20 kg/m^2, but no difference in the patients with a BMI of 30 kg/m^2.

FAMILY HISTORY AND GENETIC FACTORS

Osteoporosis is a multifactorial disorder that results from the effects of genetic and environmental factors. When comparing postmenopausal females with diagnosed osteoporosis to those without, females with osteoporosis had a significantly higher family history of osteoporosis and family history of fracture.[27] A family history of osteoporotic fracture is believed to be an underlying genetic predisposition.[6] Small stature or height is inherited. Smaller bone size can influence the risk of fracture, as bigger bones may be more resistant to breaking. The significance of heredity as a risk factor for osteoporosis has been studied. Certain disease states are genetic and have an associated risk of osteoporosis (eg, celiac disease, a disorder associated with malabsorption). Genetic factors

associated with osteoporosis may be related to peak bone mass, polymorphisms in the vitamin D receptor, genes associated with estrogen deficiency or estrogen resistance, bone morphogenetic proteins, signaling pathways, and various other bone-related proteins and receptors.[6],[28],[29]

MOBILITY AND PHYSICAL ACTIVITY

Bone mass is dependent on physical activity.[6] Prolonged immobility of a limb or prolonged bed rest can result in loss of skeletal tissue and bone mass. A number of studies have looked at the effect of exercise on bone mass. The Cochrane Database published a meta-analysis of randomized controlled trials that included different types of exercise interventions in the prevention and treatment of osteoporosis in postmenopausal females.[30] The effect of all exercise types versus control was small; there was significant improvement in BMD at the spine and trochanter, but not at the femoral neck or total hip, and there was no difference in risk of fracture. Significant effects of low-force, weight-bearing exercise, such as walking or Tai Chi, were found in the spine and wrist. A significant effect on BMD from high-force weight-bearing exercise, such as jogging, jumping, running, dancing, and vibration platform, was found at the hip. Significant effects of nonweight-bearing exercise, such as progressive resistive strengthening, were seen at the spine and the neck of the femur. Combinations of exercise types had a significant effect on BMD at the neck of the femur, spine, and trochanter and reduced the risk of fractures. BMD at the hip, however, favored control. Limitations reported by the authors include small sample size, loss of follow-up, lack of reported exercise characteristics, and heterogeneity. Although the evidence for exercise has limitations and the lasting value of exercise when stopped is not known, there is good evidence that physical activity is associated with improved health and reduced mortality and should be encouraged.[6] The NOF recommends a combination of regular weight-bearing exercise and muscle-strengthening exercise to increase strength and reduce the risk of falls and fractures.[1] These include walking, jogging, Tai Chi,

stair climbing, dancing, tennis, weight training, and other resistive exercises. The Institute for Clinical Systems Improvement (ICSI) guidelines also recommend a combination of exercise to maintain and improve bone health; impact exercise such as jogging, brisk walking, stair climbing; strengthening exercise with weights; and balance training such as Tai Chi or dancing.[25] Exercise can decrease the risk of falls by about 25%. Patients with severe osteoporosis should use caution when including exercises that increase forces on the spine, such as lifting heavy weights or forward spine flexion such as bending to touch one's toes.[23] These movements can increase the risk of fracture.

CIGARETTE SMOKING AND ALCOHOL INGESTION

Although T.J. does not smoke and only occasionally ingests alcohol, it is important to include questions concerning cigarette and alcohol use when obtaining a medical history from a person at risk for osteoporosis. Females and males who smoke have an increased risk for fractures, including hip fractures, compared with nonsmokers.[6] Smoking impairs the absorption of dietary and supplemental calcium, lowers body weight, influences estrogen metabolism, and may be directly toxic to bone cells.[25],[31]

Excessive alcohol use by both females and males is associated with decreased BMD.[32] The effect of alcohol on bone is dose dependent; consuming more than two alcoholic drinks daily significantly increases the fracture risk.[6],[32] The proposed mechanism may be a direct effect of alcohol on osteoblasts or it may be secondary to nutritional compromise that could result in impaired calcium and vitamin D intake with subsequent decrease in bone formation. The effect on bone formation has been seen even at no more than one drink per day for females and two drinks per day for males.[25] It is recommended that alcohol be limited to this amount to protect bone health and reduce the risk of falls.

DIETARY INTAKE

Dietary calcium and vitamin D are critical to bone health and are needed to strengthen bones and increase bone mass. Peak bone mass is achieved in early adulthood, and afterward, bone constantly undergoes remodeling.[22] Maintaining normal bone mass reduces the risk of osteoporosis and fracture. Females and males need adequate calcium and vitamin D intake to achieve and help maintain optimal bone mass. The Institute of Medicine (IOM), now the National Academy of Medicine, published recommendations for both calcium and vitamin D intake that would promote bone maintenance along with a neutral calcium balance based on age.[22] For males and nonpregnant females ages 19 to 50 years, an intake of 1000 mg of elemental calcium per day and 600 international units (IU) of vitamin D per day is recommended (**Table 110-2**). The National Institutes of Health (NIH) base their recommendations on the same published report.[33] The NOF has similar recommendations for calcium, however, it differs in their recommendations for vitamin D intake.[1] Vitamin D 800 to 1000 IU per day is recommended for individuals ages 50 years and older. The American Association of Clinical Endocrinologists/American College of Endocrinology also recommends similar calcium intake but recommends a maintenance of vitamin D of 1000 to 2000 IU/day to maintain serum levels above 30 ng/mL.[23] Calcium is best ingested from the diet. Significant sources of calcium include dairy products, tofu, and canned fish (**Table 110-3**). Calcium absorption from foods is ~30% but will vary depending on the food.[22] Calcium absorption also decreases with age. Absorption from dairy products or fortified juice is about 30%, but for certain green vegetables such as broccoli and kale, the absorption can be twice as high. Oxalate- or oxalic acid–containing foods can impair calcium absorption. Kale and broccoli are foods low in oxalate as are mustard and turnip greens.[31] Examples of foods that contain high levels of oxalic acid are spinach, sweet potatoes, beans, and collard greens. Even if high in calcium, oxalate impairs the absorption of calcium. Some foods high in fiber can interfere with calcium absorption; thus, intake of a variety of foods with calcium is recommended. Alcohol, caffeine from coffee or tea, protein, a high

intake of sodium, and excess dietary phosphorous all negatively affect calcium balance.[22,31]

Table 110-2
Dietary Reference Intakes for Calcium and Vitamin D

Life Stage Group	RDA Calcium	RDA Vitamin D
Males		
19–50 years	1000 mg	600 IU (15 µg)
51–70 years	1000 mg	600 IU (15 µg)
>70 years	1200 mg	600 IU (15 µg)
Females (nonpregnant)		
19–50 years	1000 mg	600 IU (15 µg)
51–70 years	1200 mg	600 IU (15 µg)[a]
>70 years	1200 mg	800 IU (20 µg)[a]

IU, International unit; RDA, Recommended dietary allowance.

[a]The National Osteoporosis Foundation recommends vitamin D 800 to 1000 IU in patients 50 years and older.

Table 110-3
Calcium Content of Selected Foods

Food	Serving Size	Calcium (mg)
Dairy		
Milk, dry nonfat	1 cup	350–450
Yogurt, low fat	1 cup	345
Milk, skim	1 cup	300
Milk, whole	1 cup	250–350
Cheese, cheddar	1 oz	211
Cheese, cottage	1 cup	211
Cheese, American	1 oz	195

Food	Serving Size	Calcium (mg)
Cheese, Swiss	1 oz	270
Ice cream or ice milk	1/2 cup	50–150
Fish		
Sardines, in oil	8 med	354
Salmon, canned (pink)	3 oz	167
Fruits and vegetables		
Calcium-fortified juices	1 cup	100–350
Spinach, fresh cooked	1/2 cup	245
Broccoli, cooked	1 cup	100
Collards, turnip greens	1/2 cup	175
Soybeans, cooked	1 cup	131
Tofu	1 cup	75
Kale	1/2 cup	50–150

Vitamin D is considered a nutrient and a regulatory hormone. It is a fat-soluble vitamin that is found naturally in very few foods but is added to certain foods and is available in supplement form. Vitamin D is a nutrient that can be synthesized in the skin through the action of sunlight, but exposure to sunlight should be limited because of the risk of skin cancers.[22] Sunlight may also not produce enough vitamin D because of differences in skin pigmentation, latitude, or use of sunscreen. Vitamin D regulates calcium and phosphate, which make it important in the development and maintenance of bone health.

It directly stimulates calcium and phosphate absorption from the intestinal tract, and with the help of PTH, it can mobilize calcium from bone or stimulate calcium reabsorption at the renal distal tubule (see also Chapter 28, Chronic Kidney Disease). Vitamin D that is found in the diet or that is synthesized from the sun must be converted to its active form, calcitriol. Two major forms of vitamin D are available. Vitamin D_3, cholecalciferol, is synthesized in the skin of humans from 7-dehydrocholesterol, is synthesized commercially, and can also be found in fatty fish, beef liver, egg yolks, and cheese. Vitamin D_2,

ergocalciferol, is plant-based and largely synthesized commercially. Both forms can be found in dietary supplements or fortified foods. Cholecalciferol and ergocalciferol are inactive until they are converted to active vitamin D first by the liver to 25-hydroxyvitamin D (25[OH]D), and then by the kidneys to 1,25-dihydroxyvitamin D, calcitriol. The serum level of 25(OH)D is considered the marker for adequate intake. The NOF recommends vitamin D intake to maintain serum 25(OH)D levels >30 ng/mL (75 nmol/L).[1] Aging, chronic renal insufficiency, intestinal disease, malabsorption, very dark skin, obesity, certain medications, and reduced sun exposure are associated with reduced serum levels of vitamin D.

T.J. is typical of the average American and has a diet low in calcium. If the calcium or vitamin D in her diet does not achieve the recommendations, supplements should be added (see **Table 110-4**; see Case 110-1, Questions 2, 3).

Table 110-4
Calcium Content in Various Supplements

Salt	Percent Calcium
Calcium carbonate	40
Tricalcium phosphate (calcium phosphate, tribasic)	39
Dibasic calcium phosphate dehydrate	23
Calcium citrate	21
Calcium lactate	13
Calcium gluconate	9

OTHER POTENTIAL RISKS

Various medications and medical conditions that have been associated with the development of osteoporosis are listed in Table 110-1.

Prevention

PREMENOPAUSAL FEMALES

CASE 110-1, QUESTION 2: Although T.J. is premenopausal, what recommendations could be made to decrease her future risk of developing osteoporosis?

Universal recommendations for the prevention of osteoporosis are adequate intake of daily calcium and vitamin D; weight-bearing, resistance, balance, and strengthening exercises; reduced alcohol consumption; and smoking cessation. T.J.'s course of action should be to maximize her peak bone mass and prevent or decrease bone loss. Her diet should consist of adequate calcium of 1000 mg and adequate vitamin D of 600 IU. T.J. should continue to exercise, developing a lifelong exercise program, and continue to refrain from smoking. T.J. should also maintain her BMI between 20 and 25 kg/m^2.

Exercise

T.J. should be encouraged to participate regularly in weight-bearing and strengthening exercises such as jogging, walking, running, biking, tennis, or weight-lifting and to continue appropriate exercise for her age throughout life. Physical activity has numerous benefits in addition to promoting bone health. Exercise enhances overall health and well-being, helps to control blood pressure, and lowers risk factors for cardiovascular disease, colon cancer, and type 2 diabetes.[31] Young females such as T.J. should be made aware that it is important to maintain regular menstrual periods. Amenorrhea because of strenuous exercise or extremely low body weight can increase the long-term risk of osteoporosis and fractures.

Dietary intake

T.J. should eat a well-balanced diet rich in fruits and vegetables, low-fat dairy products, whole grains, fish, and nuts. This will provide calcium as well as other nutrients needed for bone health. She should ensure her diet contains 1000 mg of elemental calcium and

600 IU vitamin D, optimally from dietary sources.[31] Dairy products are the major source of dietary calcium in the United States. Low-fat or nonfat versions have the full amount of calcium. Fortified juices or fortified cereals are also good sources of calcium. Although nondairy sources may contain lower amounts of calcium, they can be an important source for males or females with dietary preferences, those who cannot tolerate dairy, or who have food allergies (Table 110-3). The ingestion of foods rich in phytates and oxalates (eg, cereal grains, legumes, and nuts) may decrease calcium absorption.

If T.J. cannot meet her daily calcium requirement from dietary sources, she can use a calcium supplement. Table 110-4 lists the percentage of elemental calcium available from selected calcium salts. (See Case 110-1, Question 3, for further information on calcium supplements.)

Vitamin D is found in few foods naturally (eg, beef liver, egg yolk, salmon, tuna) but can be found in fortified juice or milk. It is difficult to quantify the amount of vitamin D obtained from sunlight. Genetic factors, skin pigment, latitude, and the use of sunscreen are all factors that affect sun exposure.[22] T.J. should be able to obtain adequate vitamin D intake from her diet. She could also add a supplement to her diet to achieve 600 IU of vitamin D daily.

Other bone-related nutrients include magnesium, phosphorus, vitamin K, and protein. Magnesium affects the concentration of PTH, is involved in the formation of bone, and is widely available in foods and fortified cereals.[34] Low dietary intake of magnesium has been associated with lower BMD, but not an increase in the incidence of hip fracture or total fractures.[35] Total daily magnesium intake was estimated in 73,684 postmenopausal females enrolled in the Women's Health Initiative Observational Study. Females who consumed magnesium in the highest quintile had a 3% higher total hip BMD and a 2% higher whole-body BMD than those in the lowest quintile. The incidence of hip fracture or total fracture was not statistically different across quintiles of magnesium intake. Calcium, as well as phosphorus, is stored in the bone. A complex balance of both is necessary for bone strength.[31] Low dietary intake of phosphorus as well as excessive intake have adverse effects on

bone. Vitamin K is also important to maintain healthy bones. Patients who are on long-term vitamin K antagonists or who have a diet low in vitamin K are at increased risk for fracture and osteoporosis, but this risk is controversial.[36] Currently, there is no strong evidence and no recommendations for supplementation.[36–38] Isoflavones are a class of phytoestrogens found in soybeans and red clover, have estrogen-like activity, and have been shown to increase bone density. There is conflicting and insufficient information on phytoestrogens to support the use of isoflavones for osteoporosis prevention.[31] Soy, however, is a good source of protein, which is also important for bone health. Calcium absorption is decreased in diets that are low in protein.

Smoking and alcohol

Smoking cessation should be encouraged in males or females who smoke. Rates of bone loss is greater in smokers than for nonsmokers, and calcium absorption may be decreased.[25] T.J. occasionally drinks alcohol and should be educated on the risk of alcohol and decreased BMD. Recommended alcohol intake should be limited to no more than one drink per day for females and two drinks per day for males.

Case 110-1, Question 3: If T.J. needs a calcium supplement, which calcium salt should be recommended?

The amount of elemental calcium in supplements varies. Two common forms of calcium supplements are calcium carbonate and calcium citrate.[22,34] The cost of calcium carbonate tends to be lower, and it contains the highest percentage of elemental calcium (40%), allowing fewer tablets per day to meet daily calcium requirements. Calcium absorption from supplements depends on the total amount of elemental calcium consumed at one time. The percentage of calcium absorbed decreases as the dose increases. Maximal absorption occurs at doses ≤500 mg at one time.[34] If T.J. needs a calcium supplement, calcium carbonate is a reasonable choice. She should be advised to take it in divided doses up to 500 mg/dose to

maximize absorption. Calcium carbonate absorption is dependent on stomach acid and should be taken with food. Calcium citrate contains less elemental calcium, 21%, is less dependent on stomach acid for absorption, and can be taken with or without food. Calcium citrate is beneficial in patients with achlorhydria, inflammatory bowel disease, or in patients taking proton pump inhibitors or histamine-2 receptor blockers. Supplements should be taken with plenty of fluids. Calcium can compete or interfere with the absorption of iron, zinc, and magnesium. Significant drug interactions can also occur, such as impaired absorption of medications, including tetracyclines, thyroid products, and quinolones (**Table 110-5**). T.J. should be informed that the most common adverse effects of calcium are constipation, GI irritation, bloating, and flatulence. Caution should be used in patients with renal insufficiency, hypoparathyroid disease, hypercalcemia, and a history of kidney stones. If T.J. or any family member has a history of urinary stones, her clinician should be aware of supplementation. T.J. should drink plenty of water throughout the day and take calcium carbonate with food to ensure absorption or switch to calcium citrate.

Table 110-5

Drug Interactions

Examples of Drug–Calcium Supplement Interactions[a]	
Allopurinol	Protease inhibitors
Bisphosphonate derivatives	Tetracycline derivatives
Calcium channel blockers	Protease inhibitors
Certain cephalosporin antibiotics	Quinidine
Corticosteroids (oral)	Quinolone antibiotics
HMG-CoA reductase inhibitors	Sucralfate
Iron salts	Thiazide diuretics
Itraconazole, ketoconazole	Thyroid products
Magnesium salts	Tetracycline derivatives
Multivitamins/fluoride (with ADE)	Vitamin D analogs

Multivitamins/minerals (with ADEK, folate, iron)	Zinc

[a]Does not include all calcium-drug.

POSTMENOPAUSAL FEMALES

CASE 110-2

QUESTION 1: T.J.'s mother, M.J., is a 53-year-old Caucasian female, who is also of small stature and low weight. She occasionally walks in the evenings. She is currently taking a calcium supplement to maintain her total calcium intake (dietary plus supplementation) of about 1 g/day. She takes over-the-counter omeprazole for her gastroesophageal reflux disease (GERD) and occasional acetaminophen for headaches. M.J. was a cigarette smoker but stopped in her late 20s and rarely drinks alcohol. She is in good health with no gynecologic surgery or major diseases. M.J. has a strong family history of breast cancer. Her last menstrual period was 6 months ago, but she began experiencing menstrual irregularity 2 years ago. M.J. has been experiencing some menopausal symptoms (hot flushes), but states that they are mild and occur only at night. M.J., worried about developing osteoporosis, decided to make an appointment with her gynecologist to discuss preventive measures. A DEXA measurement of her spine was administered, which noted her T-score to be −2.0 and a Z-score of −1.0.

In addition to the DEXA, what other information should be obtained to determine whether M.J. is at risk for developing osteoporosis or has already developed osteoporosis?

In addition to M.J.'s DEXA, a detailed medical history, including medication history (prescription and over-the-counter medications), diet, social history (smoking, alcohol) and a physical examination, which includes height, are needed along with a risk factor analysis. Diagnostic tests are indicated when there are multiple risk factors present.[1] The goals of a comprehensive evaluation are to identify modifiable risk factors, rule out potential causes of osteoporosis, and to treat if indicated.

From her history and risk factor analysis, it is determined that M.J. shares similar risk factors for osteoporosis with her daughter. In addition, she is early in the postmenopausal phase, has GERD, and

was a previous smoker. M.J. has no loss of height, does not report back pain, and does not have signs of kyphosis, all of which may be signs of osteoporosis. As part of the aging process, females may lose 1 to 1.5 inches (2.54–3.81 cm) in height because of degenerative arthritis and shrinking of intervertebral discs.[1] It is important to monitor height, as a loss of height may indicate that the patient has a vertebral fracture.

Biochemical markers of bone turnover are not needed for M.J. at this time (eg, alkaline phosphatase, calcium levels, phosphorus levels, bone-specific alkaline phosphatase, osteocalcin, propeptides of type 1 collagen, cross-linked C-terminal telopeptide, and N-telopeptide). They are not used to diagnose osteoporosis but may be used to evaluate drug therapy.[1,19]

BMD measurement would be useful in females such as M.J. It is used to screen for and monitor osteoporosis.[23] According to the American Association of Clinical Endocrinologists/American College of Endocrinology Clinical Practice Guidelines, screening is recommended in patients who are at high risk of osteoporosis, such as postmenopausal females age 50 years and older, patients treated with high-risk medications or have conditions related to bone loss, patients who weigh <127 pounds (56 kg), those with a prior fracture after age 50 not because of major trauma (excluding fingers, toes, skull), and those with excessive alcohol intake (more than three drinks per day). BMD measurement is recommended for all patients age 65 years and older.

The NOF recommends BMD testing for females age 65 years and older, males age 70 years and older, menopausal females or females in menopausal transition who are younger than age 65 and at increased risk of osteoporosis or who suffered a low-impact fracture, nonmenopausal females over age 50 and males ages 50 to 70 who have suffered a low-impact fracture or who are at risk for fracture, and adults with a condition or who take medication that is associated with low bone mass.[1] Along with evidence-based and guideline recommendations of the appropriate time to screen and monitor, insurance reimbursement plays a role in BMD testing.

BMD refers to the amount or weight of bone mass per area and is measured in g/cm^2.[23] Measurement of BMD is the gold standard for the diagnosis of osteoporosis and is reported as T-score (**Table 110-6**) and also as Z-score.[23],[25] T-score represents the number of SDs the measured BMD value is from the average value for a normal young adult of the same sex. Z-score represents the number of SDs the measured value is from the value of the average person of the same age, sex, and ethnicity.

$$\text{T-Score} = [(\text{measured BMD} - \text{young adult population mean BMD}) / \text{young adult population SD}]$$

$$\text{Z-score} = [(\text{measured BMD} - \text{age-matched population mean BMD}) / \text{age-matched population SD}]$$

Table 110-6
Definitions of Bone Mineral Density

Classification	T-Score
Normal	≥ −1.0 SD
Osteopenia (low bone mass)	−2.5 to −1.0 SD
Osteoporosis	< −2.5 SD
Severe osteoporosis	< −2.5 SD with fragility fracture

DEXA is a two-dimensional x-ray that is considered the standard for measuring BMD to diagnose or assess therapy. Central DEXA of the hip, spine, and femoral neck remain the preferred measurement for definitive diagnosis.[2] The distal third of the radius of the forearm is also used if other sites are not available.

Non-DEXA measurements are available using CT scan and ultrasound but should not be used for diagnosis or to follow a patient's response to therapy (**Table 110-7**).[6],[25] Patients should strive

to use the same testing site for monitoring BMD for the most reliable repeat measurements.[23]

Table 110-7
Techniques for Measuring Bone Mineral Density

Technique	Abbreviation	Measurement Sites
Dual-energy x-ray absorptiometry	DEXA	Hip, spine, total body
Peripheral dual-energy x-ray absorptiometry	PDEXA	Forearm, fingers, heel
Peripheral quantitative computed tomography	PQTC	Forearm, tibia
Quantitative ultrasound	QUS	Heel, tibia, patella
Quantitative computed tomography	QCT	Spine, hip
Single-energy x-ray absorptiometry	SEXA	Heel

Diagnosis of osteoporosis is defined as a T-score of −2.5 or less at the lumbar spine, total hip, or femoral neck.[23],[39] A T-score between −1.0 and −2.5 is considered low bone mass. Because there is an inverse relationship that exists between BMD and fracture risk, a low BMD is still a marker of fracture risk. The International Society for Clinical Densitometry (ISCD) recommends using Z-scores when reporting BMD in premenopausal females and males less than age 50.[39] A Z-score of −2.0 or less is below the expected range, and a Z-score > −2.0 is considered within range. It has been estimated that for every 1-point decrease in SD from the mean T-score, a 10% to 15% change may occur in BMD. The magnitude of this change can be translated into a 1.5-fold to 3-fold change in risk for fractures.[32] Repeat BMD testing should be individualized. DEXA should be repeated every 1 to 2 years until stable or improved in patients who are being treated for osteoporosis.[23],[39] Longer intervals are appropriate thereafter. For those who are at low risk and not receiving medications for osteoporosis, a repeat DEXA may be reasonable after 5 years.[32]

The World Health Organization along with several leading osteoporosis organizations developed the WHO Fracture Risk Assessment tool (FRAX®) that can be used alone or with BMD to identify fracture risk.[40] FRAX® is a computerized-based algorithm created for different populations available online at http://www.shef.ac.uk/FRAX. The FRAX® algorithm incorporates ethnicity as well as clinical risk factors (eg, age, smoking, physical inactivity, height, weight, prior fracture, parental history of hip fracture, long-term use of glucocorticoids, and comorbid conditions that have been associated with decreases in BMD) to calculate 10-year fracture risk. FRAX® has been validated in 11 different cohorts and is a valuable tool that provides information on absolute risk instead of relative risk by taking into account the impact of risk factors on fracture and death. As with many tools, there are some limitations to FRAX®. The algorithm excludes certain variables such as vitamin D deficiency, bone turnover markers, and falls. It does not take into account multiple fractures and may underestimate the risk.

FRAX® is intended to be used in postmenopausal females and males over age 50 and should not replace clinical judgment for treatment. It has not been validated in patients who have been on or who are receiving medication therapy for osteoporosis.[1]

The FRAX® tool can be adjusted for trabecular bone score (TBS) when available.[41] TBS is a measure of variations in gray level pixels in the DEXA image.[42] It is calculated using software that is installed on DEXA scanners. Although it is measured in the spine, TBS is an independent risk factor for osteoporosis-related fractures including hip fracture. Low TBS scores represent less homogenous weaker bone. When used with the FRAX® tool, TBS improves its performance.[23],[42] A low TBS increases the FRAX® 10-year fracture risk.

TBS-adjusted FRAX® when available is considered clinically relevant. It can be useful in patients where FRAX® alone may underestimate the 10-year risk of osteoporosis-related fracture.

Case 110-2, Question 2: Based on the information that you have obtained, does M.J. have osteoporosis, or is she at risk for developing osteoporosis?

M.J. is 62 inches (157.48 cm) tall and weighs 110.23 pounds (50 kg). She has a T-score of −2.0 (DEXA measurement of the spine) and a Z-score of −1.0. Using the FRAX® risk assessment tool for the U.S. population without a T-score of the femoral neck, M.J.'s 10-year probability of a hip fracture is 0.5%, and her 10-year probability of a major osteoporosis-related fracture is 5.1%. M.J.'s T-score is consistent with osteopenia or low bone mass.

M.J.'s risks include low bone mass, low body mass, a family history of osteoporosis, history of smoking, and medication that increases the risk of osteoporosis.

Case 110-2, Question 3: What preventive measures would help decrease M.J.'s likelihood of developing osteoporosis?

Exercise

M.J. goes for walks occasionally and should begin a consistent exercise program appropriate for her age and physical condition. Postmenopausal females who incorporated aerobic and weight-bearing exercises showed some improvements in BMD and reduced the risk of fractures as compared to those who did not exercise.[30] Weight-bearing exercise and resistance training may improve strength, muscle mass, flexibility, and balance and decrease M.J.'s risk for falls.[25] (Also see Case 110-1, Question 2.)

Dietary intake

Similar to T.J., it is important for M.J. to have a well-balanced diet rich in fruits and vegetables, low-fat dairy products, whole grains, fish, and nuts to provide adequate calcium and nutrients needed for bone health. The recommended daily allowance of calcium for females ages 51 to 70 is 1200 mg/day.[22] M.J.'s total calcium intake from diet and supplementation is about 1000 mg/day and should be increased so that she incorporates 1200 mg/day of calcium in her diet. She can do this by choosing calcium-containing foods (see

Table 110-3) and by taking a supplement if she cannot get adequate calcium from her diet (see Table 110-4).

It is important for M.J. to have adequate vitamin D intake in her diet. The recommended daily allowance of vitamin D for females between 51 and 70 age is 600 IU/day, and for females over age 70, the recommended daily allowance is 800 IU/day. The NOF recommends 800 to 1000 IU/day for males and females over age 50.[1]

Expert consensus opinion has made recommendations for serum 25(OH) vitamin D levels for bone health.[22] Levels <20 ng/mL (50 nmol/L) suggest insufficiency, whereas levels of 29 to 32 ng/mL (70–80 nmol/L) suggest adequate stores. There is currently limited evidence to attempt to achieve serum 25(OH) vitamin D levels above 60 ng/mL (150 nmol/L). (For further information, see Case 110-1, Question 2.) A serum 25(OH) vitamin D level should be drawn and M.J. should receive a vitamin D supplement to achieve a serum 25 (OH) vitamin D level of 30 ng/mL (75 nmol/L) if the level is found to be insufficient.

Although calcium and vitamin D are important for bone health, they should not be used instead of drug therapy to treat osteoporosis but as part of an overall plan to help improve bone health.

Pharmacologic Prevention

ESTROGEN/PROGESTIN THERAPY

Case 110-2, Question 4: Because a rapid rate of bone loss is seen during menopause when estrogen decreases, should estrogen therapy (ET) or estrogen + progesterone therapy (EPT) be considered for M.J.?

An estimated 10% to 15% of a female's bone mass is estrogen dependent.[43]

Estrogens are important in bone formation, resorption, and maintaining bone mass, whereas menopause is associated with a decrease in estrogen and an increase in bone loss.[14,18]

The National Osteoporosis Risk Assessment Study and the Million Women Study, both large observational studies by design, found that EPT or ET provided significant relative-risk reductions in fracture.[44,45] These results were confirmed by the Women's Health Initiative (WHI) with both the EPT and ET arms, showing significant risk reductions in hip, vertebral, and total fractures compared with placebo.[46,47]

Previously, ET or EPT would have been considered first-line treatment for the prevention of osteoporosis in a postmenopausal female such as M.J., who has an intact uterus and is at risk for osteoporosis based on risk factors and T-score. In the WHI, conjugated equine estrogen (CEE) alone and CEE with medroxyprogesterone (CEE + MPA) were shown to decrease the risk of hip, vertebral, and total fractures in postmenopausal females; however, the intervention phases were ended early because coronary heart disease (CHD), stroke, deep vein thrombosis (DVT), pulmonary embolism (PE), and breast cancer were significantly increased in the CEE + MPA group, and rates of stroke were significantly increased in females on CEE alone (also see Chapter 51, The Transition through Menopause).[46,47] The findings from the WHI do not support the use of ET or EPT for the prevention of osteoporosis. Since the publication of the Heart and Estrogen/Progestin Replacement Study (HERS) I and HERS II and the NIH WHI, health care providers are less likely to prescribe ET or EPT for the sole purpose of osteoporosis prevention or to continue its use after a female no longer needs EPT or ET for postmenopausal symptoms such as hot flushes.[48–50]

EPT is approved for the prevention of osteoporosis in postmenopausal females with a uterus, and ET is approved for postmenopausal females without a uterus.[32] When prescribed for osteoporosis prevention, ET and EPT should be used at the lowest effective doses and the shortest duration indicated. Longer therapy should only be prescribed in females who have failed other osteoporosis therapies or when other osteoporosis therapies are contraindicated and when it can be determined that the benefits outweigh the risks. M.J. does not have bothersome symptoms of

menopause; therefore, ET or EPT would not be appropriate at this time.

Contraindications to estrogen use

Case 110-2, Question 5: If M.J. developed bothersome symptoms of menopause, would ET or EPT be appropriate to treat symptoms and prevent osteoporosis?

Contraindications to EPT or ET include pregnancy; active or history of DVT or PE; active or recent (eg, within the past year) arterial thromboembolic disease (eg, stroke, myocardial infarction); undiagnosed abnormal genital bleeding; known, suspected, history of breast cancer; known or suspected estrogen-dependent neoplasia; liver dysfunction or disease; or known hypersensitivity to the product or any of its ingredients.[51] In addition, EPT and ET should be used with caution in those with a history of asthma, diabetes mellitus, migraine, epilepsy, systemic lupus erythematous, porphyria, and hepatic hemangiomas. Patients on EPT or ET are at increased risk for cancer, including endometrial (if not on EPT), breast (for EPT), and ovarian cancer as well as increased cardiovascular events, thromboembolic disease, stroke, gallbladder disease, and dementia (also see Chapter 51, The Transition through Menopause).

M.J. stated that she has a strong family history of breast cancer and starting EPT or ET would not be the treatment of choice for the prevention of osteoporosis.

TREATMENT OF LOW BONE MASS

Case 110-2, Question 6: Should pharmacologic therapy be considered for the prevention of fracture in postmenopausal females such as M.J.?

Osteoporosis drug therapy should be considered in postmenopausal females and males age 50 with a vertebral or hip fracture and those

with a T-score of −2.5 or lower at the lumbar spine, femoral neck, total hip, or third of the radius. Therapy is not indicated for most patients with low bone mass. Pharmacologic therapy is indicated in patients with low bone mass who have had a fracture or are at high risk of fracture; those with a T-score of −1.0 to −2.5 who have had a fragility fracture of hip or spine, and those with a T-score of −1.0 to −2.5 who have a 10-year fracture risk of ≥20% (spine, hip, shoulder, wrist) or risk of ≥3% (hip) calculated using FRAX® or TBS-adjusted FRAX®.[1,23]

Although M.J. is at risk of an osteoporotic fracture, her 10-year probability of a hip fracture is 0.5%, which is <3%, and her 10-year probability of a major osteoporosis-related fracture is 5.1%, which is <20%. The FRAX® tool is important for assessing fracture risk and used to weigh the potential benefit of therapy. Because her fracture risk is low and pharmacologic therapy for osteoporosis is associated with risk of adverse effects, M.J. should continue lifestyle changes to promote bone health. Patient adherence to these changes should be checked at all office visits.

CASE 110-3

QUESTION 1: M.J.'s sister, S.D., is a 62-year-old Caucasian female. She is 121.25 pounds (55 kg), 62 inches (157.48 cm) tall, attends yoga and fitness classes three to four times per week, and states she feels well. She recently started a calcium and vitamin D supplement every day as recommended by her primary care physician. She has never smoked, does not drink alcohol, and is on no other medications. Her last menstrual period was 8 years ago. She has a history of fracture of the distal forearm 2 years ago. A recent BMD of the spine and hip were −2.6 and −2.0, respectively. S.D., like M.J., has a strong family history of breast cancer.

Is calcium and vitamin D alone or together enough to prevent fracture in patients like S.D.?

CALCIUM AND VITAMIN D IN THE TREATMENT OF OSTEOPOROSIS

Although calcium and vitamin D are essential for bone health, there is inconsistent evidence on the effect of these nutrients on

preventing fracture. When taken alone or together, they are not enough to treat osteoporosis.

A network meta-analysis that included 25 randomized controlled trials was conducted to evaluate the fracture risk of using different doses of vitamin D, calcium, or their combination in community-dwelling older persons.[52] Participants were separated into groups: high- and low-dose calcium (≥ and <800 mg) and high- and low-dose vitamin D (≥ and <800 IU). For the outcome of total fracture (*N* = 24,965 from 18 studies), there were no differences in fracture rate in patients using vitamin D, calcium, or their combination by direct and indirect comparisons. No difference was found for hip fracture (*N* = 41,845 from 16 studies) or for vertebral fracture (*N* = 17,612 from 12 studies). Removing low-quality trials did not affect the results.

A Cochrane review of vitamin D and vitamin D analogs for preventing fractures in postmenopausal females and older males concluded that vitamin D alone is not likely to reduce the risk of fracture, but when taken in conjunction with calcium, the risk of fracture and bone loss is slightly reduced.[53] Results of other meta-analyses support these findings.[54],[55]

S.D. should continue adequate intake of vitamin D and calcium, but as they may be insufficient to adequately prevent fracture, pharmacotherapy should be considered.

Case 110-3, Question 2: Should S.D. be treated with a bisphosphonate for osteoporosis?

S.D. has a T-score of the spine lower than −2.5, a previous fracture, and a 10-year probability of hip fracture that is >3%. Pharmacologic treatment is indicated.

Bisphosphonates are considered first-line therapy for the prevention and treatment of osteoporosis. Alendronate ibandronate, risedronate, and zoledronic acid are indicated for the treatment of osteoporosis in postmenopausal females like S.D. They have multiple administration options available that may be beneficial in enhancing adherence in certain patients, and all are available as

generic medications. Agents indicated for the treatment and prevention of osteoporosis can be found in **Table 110-8**.[56]

Table 110-8
Medications Approved for Prevention and Treatment in Postmenopausal Osteoporosis

Class	Medication	Prevention	Treatment
Bisphosphonates	Alendronate	5 mg PO daily 35 mg PO weekly	10 mg PO daily 70 mg PO weekly
	Alendronate/ cholecalciferol		70 mg/2,800 IU PO weekly 70 mg/5600 IU PO weekly
	Ibandronate	150 mg PO monthly	150 mg PO monthly
	Risedronate	5 mg PO daily 35 mg PO weekly 150 mg PO monthly	5 mg PO daily 35 mg PO weekly 35 mg DR PO weekly 150 mg PO monthly
	Zoledronic acid	5 mg IV every other year	5 mg IV yearly
Selective estrogen-receptor modulators (SERMs)	Raloxifene	60 mg PO daily	60 mg PO daily
Polypeptide hormone	Calcitonin	Not indicated	100 IU IM or SC once daily, every other day, or three times per week 100 IU intranasally in one nostril daily
Monoclonal antibody	Denosumab	Not indicated	120 mg SC every 6 months
Parathyroid hormone	Teriparatide Abaloparatide	Not indicated Not Indicated	20 µg SC once daily 80 µg SC once daily
Sclerostin inhibitor	Romosozumab	Not indicated	210 mg SC monthly for 12 doses as two separate 105 mg/1.17 mL injections
Estrogen	Conjugated estrogen	When other treatments are not appropriate (without uterus)	Not indicated
	Estrogen + progestin	When other treatments are not appropriate (with uterus)	Not indicated
	Conjugated estrogen + bazedoxifene	0.45 mg/20 mg PO daily	Not indicated

DR, delayed release; IM, intramuscular; IU, international units; IV, intravenous; PO, by mouth; SC, subcutaneous. DR, ; IM, intramuscular; IU, international units; IV, intravenous; PO, by mouth; SC, subcutaneous.

The effect of bisphosphonates is because of their ability to bind bone mineral and inhibit osteoclast activity, thereby reducing bone resorption.[57] Alendronate, ibandronate, risedronate, pamidronate, and zoledronic acid are aminobisphosphonates with a greater selectivity for the antiresorptive surfaces of the bone because of changes in the nitrogen-containing side chain of the compounds.[58] Bisphosphonates have high affinities for bone hydroxyapatite and can be incorporated into bone. They concentrate in mineral tissue

and interfere with the osteoclast-mediated bone resorption to cause osteoclast apoptosis, decreased bone turnover, resulting in decreased fracture rates in postmenopausal females who are at risk for osteoporosis.

Because of their incorporation into bone, bisphosphonates have long half-lives, estimated to be 1 to 10 years. Unlike etidronate (a non-aminobisphophonate), aminobisphosphonates do not inhibit bone mineralization, which could lead to osteomalacia.

Bisphosphonates

Alendronate

Alendronate was the first bisphosphonate approved for the treatment of postmenopausal osteoporosis in 1995 and is available as a daily or weekly tablet.[59] Many clinical trials have been published regarding the use of alendronate in the treatment of osteoporosis. In a Cochrane review of 11 randomized controlled trials and ~12,000 postmenopausal females who had previous fracture or whose BMD was >2 SD below the mean, alendronate reduced the risk of vertebral fracture (NNT 16), nonvertebral fracture (NNT 50), wrist fracture (NNT 50), and hip fracture (NNT 100).[60] Compared to placebo, alendronate reduces the risk of vertebral fracture by 40% to 64%, nonvertebral fracture by 11% to 49%, and hip fracture by 21% to 55% over 3 years.[60],[61] Alendronate is well tolerated, and adverse events reported in clinical trials were similar to placebo.

Ibandronate

MOBILE, a randomized controlled, noninferiority study, included 1609 postmenopausal females ages 55 to 80 with osteoporosis and compared daily ibandronate (2.5 mg/day) to three different monthly regimens: ibandronate 50 mg given on two consecutive days per month and 100 mg and 150 mg once monthly.[62] All monthly regimens were at least as effective as daily ibandronate after 1 year. At 2 years, the mean increase in BMD of the lumbar spine seen in the ibandronate 50 mg on two consecutive days per month was (5.3%), ibandronate 100 mg/month (5.3%), ibandronate 150

mg/month (6.4%) as compared to ibandronate 2.5 mg taken daily (4.8%). Increases were seen in the total hip, trochanter, and femoral neck, with ibandronate 150 mg/month being the most significant.

In a 5-year, long-term extension (MOBILE LTE), increases in BMD that were achieved during the MOBILE study were maintained, and further increases were seen in lumbar spine BMD.[19] Minor changes were seen in the femoral neck and trochanter. Overall, adverse effects of monthly ibandronate were similar to daily ibandronate. Benefits in BMD changes, and decreases in bone turnover markers were greatest for ibandronate 150 mg/month.

Ibandronate has also been studied as an intravenous (IV) formulation of 3 mg administered every 3 months.[63] One-year results from the Dosing Intravenous Administration (DIVA) study improved BMD in the lumbar spine (4.5% vs 3.5%) and the total hip (2.1% vs 1.5%) to a similar if not greater degree than daily oral tablets.

Ibandronate is available as a daily or monthly tablet and a 3-mg quarterly IV injection.[64] Compared to placebo, daily oral ibandronate significantly decreases vertebral risk fracture 52% to 62% over 3 years.[61],[65] No statistically significant decreases in nonvertebral or hip fracture have been found using ibandronate.[66] However, in a subgroup analysis of two noninferiority trials, higher doses of ibandronate (150 mg once monthly, 3 mg IV quarterly, and 2 mg IV every 2 months) reduced the risk of nonvertebral fracture compared to lower doses of ibandronate HR 0.620 (0.395–0.973).

Risedronate

In a study of postmenopausal females who were at least age 50 years, were postmenopausal for five or more years, and had osteoporosis, 75 mg of risedronate on 2 consecutive days a month (2CDM) was as safe and effective as risedronate 5 mg/day for 12 months.[67] At 2 years, lumbar spine BMD increases of 4.2% in the 2CDM and 4.3% in the 5-mg/day were observed.[68] There were no statistically significant differences in BMD changes in lumbar spine, proximal femur, and bone turnover markers. Adverse effects in both groups were similar.

In a study that compared risedronate 5 mg/day and 150 mg/month in postmenopausal females with osteoporosis, similar increases in lumbar spine BMD from baseline were observed (3.4%, 3.5%, respectively) after 1 year, and there was no difference in the new incidence of vertebral fractures.[69] There were similar changes in biochemical bone turnover markers. Adverse effects were similar, with a higher incidence of constipation in the 5-mg/daily group and diarrhea in the 150-mg/monthly group.

Risedronate is available as an oral tablet in four different doses; administered daily, weekly, monthly, or two consecutive days monthly.[70] Similar to alendronate, risedronate significantly reduces the rate of vertebral, nonvertebral, and hip fractures.[61],[71] Most trials used doses of 5 mg daily. Although they were not of high quality, in head-to-head trials comparing different dosing schedules, there were no statistical differences in the dosing regimens.[61] Comparing risedronate to placebo, the reduction in the risk of vertebral fracture ranged from 39% to 69%, even among subgroups with mild to severe renal impairment. The reduction in the risk of nonvertebral fracture ranged from 19% to 60%, and the reduction in the risk of hip fracture from 26% to 40%. Adverse events reported in clinical trials were similar to placebo.

Zoledronic Acid

Zoledronic acid is an IV bisphosphonate that was initially approved for osteoporosis treatment and later received the U.S. Food and Drug Administration (FDA) approval for osteoporosis prevention in postmenopausal females.[1]

In a 2-year study of zoledronic acid for the prevention of bone loss in postmenopausal females with low bone mass, 581 females were randomized to receive zoledronic acid 5 mg IV at baseline and 12 months (2 × 5 mg), zoledronic acid 5 mg IV at baseline only and placebo at 12 months, or placebo at baseline and at 12 months.[72] At 2 years, BMD was significantly increased in the lumbar spine in the (2 × 5 mg; 5.18%), (5 mg 4.42%) as compared to placebo (−1.32%). At 2 years, BMD also increased at the proximal femur sites (2 × 5

mg; total hip 2.91%, femoral neck 2.2%, trochanter 4.83%); (5 mg; total hip 2.28%, femoral neck 1.64%, trochanter 4.16%).

Zoledronic acid is available as a 5-mg IV infusion given over a 15-minute period once yearly for the treatment of osteoporosis.[73] It significantly reduces the risk of vertebral (NNT 14), nonvertebral (NNT 38), and hip fracture (NNT 98) similarly to that achieved by alendronate or risedronate.[74],[75] Zoledronic acid was associated with atrial fibrillation in a large trial of postmenopausal females diagnosed with osteoporosis but not in a subsequent study of postmenopausal females with recent hip fracture.[73],[74] It is less likely to cause GI symptoms than oral bisphosphonates; however, it is associated with injection reactions such as fever (18%), myalgia (9%), and flu-like symptoms (8%) that typically resolve within 3 days but can last up to 2 weeks. There is an increased risk of hypocalcemia following injection compared to placebo. Zoledronic acid is contraindicated in patients with acute renal impairment, patients with creatinine clearance <35 mL/minute, and in patients with hypocalcemia.

In a Health Technology Assessment by the National Institute for Health Research, a systematic review and network meta-analysis were conducted to determine the safety and effectiveness of alendronate, risedronate, ibandronate, and zoledronic acid on fragility fracture.[76] It included studies in females age 65 years and older and males age 75 years and older, and females age 64 years and younger and males age 74 years and younger with risk factors for osteoporosis. A total of 46 randomized controlled trials were included. All bisphosphonates were effective in reducing vertebral fracture compared to placebo, but only alendronate, risedronate, and zoledronic acid reduced nonvertebral fractures compared with placebo (**Table 110-9**). Fewer head-to-head trials were available for analysis, but when comparing bisphosphonates to each other, no bisphosphonate was significantly more effective than another.

Table 110-9
Effect of Bisphosphonates Versus Placebo on Fracture Prevention Citation[76]

Treatment	Vertebral Fracture HR (95% CI)	Nonvertebral Fracture HR (95% CI)
Risedronate	0.50 (0.38-0.66)	0.72 (0.53-0.89)
Alendronate	0.45 (0.35-0.58)	0.80 (0.65-0.94)
Zoledronic Acid	0.41 (0.28-0.56)	0.75 (0.61-0.91)
Ibandronate 150 mg/month	0.45 (0.24-0.81)	0.80 (0.53-1.36)

There were no serious adverse effects reported in the randomized controlled trials: there was no significant difference in participants withdrawing because of adverse effects; oral bisphosphonates had similar incidence of GI events; zoledronic acid was associated with influenza-like symptoms; and there were no significant differences in mortality. Authors report, however, that prescription monitoring data and observational studies indicate that a higher number of adverse effects, including serious adverse effects, are associated with bisphosphonates.

Oral bisphosphonates are first line and are the most commonly prescribed medications for the treatment of osteoporosis. The decision to start medication therapy for the treatment of osteoporosis prevention in postmenopausal females should involve both the patient and physician. S.D. has been diagnosed with osteoporosis, and her risk of recurrent fracture is high. Bisphosphonates are effective for secondary prevention after a first fracture. Oral alendronate or oral risedronate would be the bisphosphonate of choice for S.D. based on their availability and convenience. Zoledronic acid can be considered if S.D. cannot tolerate oral bisphosphonates.

Length of treatment

The incorporation of bisphosphonates into bone results in a reservoir of available drug that is slowly released over time.[57],[77],[78] The peak effect of reducing bone turnover markers occurs in 3 to 6 months and continues for months to years with discontinuation. Approval studies in the United States were for 3 to 4 years; however, extension studies suggest longer efficacy.[79–82] Because the risk of

adverse effects increases with longer duration, it is of interest to determine the optimum duration of treatment.

In the Fracture Intervention Trial Long-term Extension (FLEX) of the original Fracture Intervention Trial (FIT), the effects of continuing alendronate were compared to the effects of stopping alendronate after 5 years of treatment.[79] Statistically significant bone loss occurred (2%–3% more than those who took alendronate for 10 years) when females were switched to placebo after 5 years of alendronate therapy; however, BMD remained well above FIT baseline. A gradual rise was seen in biochemical markers of bone turnover, and there were no significant differences seen in clinical or nonvertebral fractures. There was a slightly higher risk of clinically detected vertebral fractures, in the placebo group (females who had discontinued alendronate therapy after 5 years) compared to the groups who continued alendronate, suggesting that females at high risk for vertebral fracture or with T-scores < −3.5 may benefit from continued bisphosphonate therapy.

The long-term effects of risedronate 5 mg/daily on bone were studied in females with osteoporosis who were in the Vertebral Efficacy with Risedronate Therapy-North American (VERT-NA) study who took risedronate for up to 5 years.[83] In biopsies of the iliac crest that were taken at 3 and 5 years, changes in bone mineral and collagen were preserved in the risedronate groups as compared to maturation that was observed with placebo. The FLEX and VERT-NA studies suggest that females with good response to bisphosphonate therapy who are not at high risk for fracture may be able to take a “drug holiday” (eg, 1 year off therapy) after 3 to 5 years of treatment.[84] Females who are able to reach a T-score of > −2.5 may be able to discontinue therapy for several years.

In an extension of the HORIZON-Pivotal Fracture Trial, long-term effects of zoledronic acid up to 6 years (Z6) were compared to patients who had no further treatment after 3 years (Z3P3).[85] Over the 3-year extension, there was a significant difference in BMD. Those patients who received zoledronic acid for 3 years lost BMD (−0.80%), and those who continued for 6 years gained BMD (+0.24%). Over the 6-year period, the gain was 3.1% and 4.5% for 3

years and 6 years, respectively. Nonclinical morphometric vertebral fracture risk (those which reduce vertebral height) was significantly lower for Z6 versus Z3P3 (3% vs 6%, *P* = .35), but there was no significant difference in clinical vertebral or nonvertebral fracture. A further extension compared 9 years of zoledronic acid to 6 years and found no significant difference in BMD or fracture.[82] Authors suggest that treatment with zoledronic acid for six annual infusions can be stopped for up to 3 years without apparent reduction of efficacy.

According to the American Association of Clinical Endocrinologists/American College of Endocrinology Clinical Practice Guidelines, it is reasonable to consider a drug holiday from oral bisphosphonates after 5 years in lower-risk patients, those who have not had a fracture, or T-score is > −2.5.[23] If risk remains high, continue for an additional 5 years. For high-risk patients, a drug holiday from oral bisphosphonates can be considered after 6 to 10 years. In patients taking zoledronic acid, a drug holiday after 3 years can be considered if risk of fracture is no longer high but continuing until 6 years if patients remain at high risk. For non-bisphosphonate treatments, a drug holiday is not recommended.

The European Menopause and Andropause Society (EMAS) published a statement on the use of drug holidays in bisphosphonates and denosumab. The phrase drug holiday arose from the idea that stopping medication treatment for a period of time may reduce long-term adverse effects while preserving the benefit on fracture risk. Major concerns of therapy with bisphosphonates and denosumab are atypical fractures and osteonecrosis of the jaw. EMAS suggests that a drug holiday should be considered for alendronate and risedronate therapy for more than 5 years and zoledronic acid for more than 3 years. No suggestions could be made for ibandronate. A drug holiday can also be considered for patients without fracture before or during therapy who are age 70 years and younger with a femoral neck T-score of ≥ −2.5. Authors state that although the length of discontinuation is unclear, a 2- to 3-year holiday would be reasonable. Patient characteristics, BMD, bone turnover markers, and fracture risk should be used to guide the decision on the appropriate length of time and whether to

discontinue therapy. There are no suggestions for the discontinuation of denosumab, as it can result in a rapid decline of BMD and a potential increased risk of fracture.

If tolerated, S.D. should continue therapy of alendronate or risedronate for up to 5 years; however, if a patient has prodromal pain in the thigh or leg or has suffered an atypical fracture while on bisphosphonate therapy, it would be reasonable to discontinue therapy and evaluate.[70]

CASE 110-3, QUESTION 3: What are the potential adverse effects of bisphosphonates?

Adverse Effects

Adverse reactions reported in postmarketing surveillance and outside of clinical trials suggest oral bisphosphonates are strongly associated with upper GI events.[59,64,70] Monthly doses may be slightly better tolerated than daily, but common adverse effects associated with the use of oral bisphosphonates include GI symptoms such as acid regurgitation, dysphagia, abdominal distension, gastritis, nausea, dyspepsia, flatulence, diarrhea, and constipation. The risk of GI intolerance may lead to less common but more severe development of esophagitis, esophageal ulcers, esophageal stricture or perforation, gastric or duodenal ulcers, and possibly esophageal cancer.[59,70] Patients with GERD or patients who cannot remain upright after dosing may not be candidates for oral bisphosphonate therapy because of gastric irritation.

Adverse effects are greater in patients who lie down after taking oral bisphosphonates, who fail to swallow the medication with a full glass (6–8 ounces) of water, or who continue to take the medication after developing symptoms suggestive of esophageal irritation. As similar GI events have been reported with oral bisphosphonates, the FDA requires a medication guide to be provided at the time these medications are dispensed.[86] A medication guide will address issues that are specific to bisphosphonates and are intended to help patients better understand treatment, adverse effects, and

adherence (see the section on Dosing). In addition to GI effects, hypocalcemia, musculoskeletal pain, headaches, and rashes have been noted.

Both IV and oral bisphosphonates are associated with osteonecrosis of the jaw (ONJ), a serious but rare adverse event.[73] It was first reported in a series of patients with cancer receiving IV bisphosphonates. Risk factors for osteonecrosis of the jaw include the diagnosis or previous history of cancer; invasive dental procedures; concurrent use of chemotherapy, corticosteroids, or angiogenesis inhibitors; poor oral hygiene; preexisting dental disease or infection; anemia; and coagulopathy. The risk of ONJ increases at higher doses and with duration of exposure.

Bisphosphonates are associated with atypical fractures of the femoral shaft.[25],[73] A warning is included in the manufacturers' information for all bisphosphonate drugs that are indicated for the prevention or treatment of osteoporosis. A safety review of oral bisphosphonates and atypical subtrochanteric femur fractures by the FDA is also ongoing.[88] A clear connection has not been found. The mechanism of action is not clear; however, bone is normally subject to microdamage with everyday stresses, and this initiates bone remodeling.[89] Antiresorptive agents may oversuppress bone turnover, causing microdamage to accumulate, which may lead to brittle bone and an increased risk of fracture. Lee et al[89] conducted a meta-analysis that included nine observational studies and one randomized controlled trial; a total of 658,497 patients. The results were statistically significant for increased risk of subtrochanteric or diaphyseal fracture with bisphosphonate use (adjusted odds ratios [AOR] = 1.99, 95% confidence intervals [CI] = 1.28–3.10), subtrochanteric fractures AOR = 2.71 (95% CI, 1.86–3.95), and diaphyseal fractures AOR = 2.06 (95% CI, 1.70–2.50). The analysis was limited by the multiple study designs, varying lengths of follow-up, and different patient populations leading to high heterogeneity. The pooled results of combined subtrochanteric or diaphyseal fracture and subtrochanteric fracture results had significant heterogeneity (84.3% and 83.6%, respectively). The results for diaphyseal fracture had moderate heterogeneity (29.7%). The overall

risk is low compared to osteoporotic fracture. In a nested case–control study of 52,595 females ages 68 years and older who took at least 5 years of bisphosphonate therapy, the subtrochanteric or femoral shaft fracture occurred in 71 (0.13%) during the subsequent year and 117 (0.22%) within 2 years.[90] The results were similar to the meta-analysis. Compared with no use or transient use, the use of bisphosphonates for 5 years or longer was associated with a significantly increased risk of atypical hip or femur fracture (odds ratio [OR] = 2.74; 95% CI, 1.25–6.02). Duration <5 years was not associated with an increased risk of fracture.

Controversial atrial fibrillation results in the zoledronic acid trials prompted an investigation by the FDA.[87] Following an analysis of clinical trials comparing alendronate, ibandronate, risedronate, and zoledronic acid to placebo, the FDA stated that there was no clear association of risk for atrial fibrillation in male and female patients treated with bisphosphonate drugs. Additional adverse effects reported with zoledronic acid are pyrexia, headache, pain in extremity, flu-like illness, and eye inflammation.[73]

Dosing

Alendronate is approved for the treatment of osteoporosis at 10 mg PO daily and 70 mg PO weekly and prevention of osteoporosis in doses of 5 mg PO daily and 35 mg PO weekly. Alendronate is also available with cholecalciferol in a 70-mg/2800 IU and 70-mg/5600 IU PO weekly tablet. Ibandronate is approved for prevention and treatment at 2.5 mg PO daily and 150 mg PO monthly. Risedronate is approved for prevention and treatment at 5 mg PO daily, 35 mg PO weekly, and 75 mg PO on two consecutive days each month and 150 mg PO monthly. The delayed-release formulation of risedronate is not indicated for the prevention of postmenopausal osteoporosis. Zoledronic acid is administered at 5 mg IV every year for treatment and every 2 years for prevention over no <15 minutes.[91] Selecting the appropriate dosing option may improve adherence to therapy.

Oral bisphosphonates are poorly absorbed and under ideal conditions have an absorption of <1%.[57] Patients should be

instructed to take most bisphosphonates with 6 to 8 ounces of water early in the morning on arising and at least 30 minutes (60 minutes for ibandronate) before ingesting food, beverage, or other medications. Risedronate is also available as a 35-mg delayed-release tablet that should be taken once weekly after breakfast. Patients should not lie down but should stay fully upright for at least 30 minutes (60 minutes for ibandronate) after ingesting an oral bisphosphonate to prevent esophageal irritation or ulceration and to ensure appropriate bioavailability. With all bisphosphonates, patients should ingest adequate calcium and vitamin D, but should not take the calcium or vitamin D at the same time as the oral bisphosphonates because they may decrease the absorption of bisphosphonates.

Contraindications and Precautions

Hypocalcemia should be corrected before beginning therapy, and all patients on bisphosphonates should receive adequate calcium and vitamin D through diet or supplements. Patients on loop diuretics should be monitored for hypocalcemia. Patients receiving zoledronic acid should be appropriately hydrated, the infusion given over no <15 minutes, then followed by a 10-mL of normal saline flush.[73] To reduce the incidence of acute-phase reaction symptoms, acetaminophen may be given postinfusion.

Although no dosage adjustments are recommended for patients with mild renal insufficiency, alendronate and zoledronic acid are not recommended in patients with creatinine clearance <35 mL/minute, and ibandronate and risedronate are not recommended in patients with creatinine clearance <30 mL/minute.

Case 110-3, Question 4: Should an SERM such as raloxifene be considered for the prevention of osteoporosis in S.D.?

Selective estrogen-receptor modulators

Raloxifene

Raloxifene is a benzothiophene second-generation SERM with both agonist and antagonist action on select estrogen target tissues.[92],[93] Raloxifene binds to estrogen receptors (ERs) resulting in estrogen agonist effect in bone and lipid metabolism and estrogen antagonist effect in breast and endometrial tissue.[93] Tamoxifen is also an SERM, but differs from raloxifene in that it has agonistic effects on endometrial tissue and raloxifene does not. Tamoxifen is indicated for the prophylaxis and treatment of breast cancer and is not indicated for postmenopausal osteoporosis prevention. Raloxifene's agonist activity on bone tissue is believed to effect osteoclastogenesis, leading to a reduction in bone resorption and a decreased rate of bone turnover, increasing BMD.[93],[94] In a study of 601 postmenopausal females age 45 to 60 with normal to low BMD, patients were randomized to receive raloxifene 30 mg, 60 mg, 150 mg or placebo daily for 2 years.[94] Significant increases in BMD of the lumbar spine (1.6%, placebo −0.8%), hip (1.6%, −0.8%), femoral neck (1.2%, placebo −1.3%), and total body (1.4%, placebo −0.6%) were observed, along with decreases in bone turnover markers, serum concentrations of total cholesterol, and low-density lipoprotein (LDL). No significant differences were observed in endometrial thickness.

Jolly et al conducted a 2-year extension study of two 3-year prospective, randomized, double-blind, placebo-controlled trials of raloxifene for the prevention of postmenopausal osteoporosis.[95] The study included 328 females from the initial 1145 core study age 45 to 60. After 5 years of therapy with raloxifene 60 mg daily, bone turnover markers decreased, BMD of the lumbar spine increased (2.8%), and total hip BMD increased (2.6%) as compared to placebo. In females with osteopenia of the lumbar spine, 2.5% developed osteoporosis in the lumbar spine as compared to 18.5% of those who took placebo. There were significant reductions in total cholesterol and LDL, but not high-density lipoprotein (HDL) or triglycerides. No significant endometrial differences were reported as compared to placebo. Females with osteopenia who took raloxifene 60 mg daily for 5 years were 87% less likely to progress to osteoporosis at the lumbar spine than those on placebo. Females

with normal BMD were 77% less likely to progress to osteopenia after 5 years of raloxifene 60 mg daily. There was a statistically significant increase in the incidence of hot flashes (raloxifene 28.8%; placebo 16.8%).

The Efficacy of Fosamax versus Evista Comparison Trial (EFFECT) was a randomized, double-blind clinical trial including 487 postmenopausal females with low bone density of the spine or hip (T-score ≤ 2.0). Efficacy and tolerability of alendronate was compared to raloxifene.[96] Patients were randomly assigned to either alendronate 70 mg weekly and daily placebo identical to raloxifene or raloxifene 60 mg daily and weekly placebo identical to alendronate for 12 months. After 1 year, increases in BMD were greater for alendronate than raloxifene in the lumbar spine (4.8% vs 2.2%, respectively; $P < .001$) and total hip (2.3% vs 0.8%, respectively: $P < .001$). Tolerability and GI effects were similar in both groups; however, significantly higher reports of vasomotor symptoms came from the raloxifene group.

In other clinical trials, females who took raloxifene had an increased risk of DVT and PE.[97]

A paradox still exists regarding how raloxifene can decrease vertebral fractures by up to 41% while increasing BMD by only 2% to 3%, rates that are lower than those noted for ET, EPT, or alendronate.[98] In addition, raloxifene has not been observed to have a significant effect on hip fractures when compared to other agents. The antifracture effect of raloxifene on vertebral fractures may occur secondary to normalization of the high turnover rate of cancellous bone, which then prevents further disruption of bone microarchitecture.[99] This may occur through raloxifene binding at estrogen β-receptor sites that are predominantly in cancellous bone, whereas α-receptors are predominantly in cortical bone. Thus, bone type and ER are different in the hips compared with vertebrae. In addition, a less potent antiresorptive agent, such as raloxifene, may help prevent vertebral fractures but not hip fractures because the threshold for preventing osteoclast activity in cancellous bone (which is predominant in vertebrae) may be lower than in cortical bone

(which predominates in hips). For these reasons, it may require a more potent antiresorptive agent to increase BMD in the hips.

Raloxifene might be considered for osteoporosis prevention in a female such as M.J., even with her strong family history of breast cancer. This latter recommendation is based on results from the MORE trial.[98] A 76% decrease was noted in risk for invasive breast cancer in postmenopausal females with osteoporosis (mean age 66.5 years) who received raloxifene for 3 years. A total of 7705 females were assigned to raloxifene groups (60 mg twice daily or 60 mg daily) or a placebo group. Of those enrolled in either raloxifene group (*N* = 5129), only 13 cases of breast cancer were reported versus 27 that occurred in the 2576 females in the placebo group. Postmenopausal females over 50 with low bone mass, such as M.J., are candidates for osteoporosis prevention therapy if they have a 10-year hip fracture probability of 3% or greater or a 10-year major osteoporosis-related fracture probability of 20% or greater based on the WHO FRAX®.[1]

Raloxifene 60 mg PO daily is indicated for the prevention of osteoporosis in postmenopausal females.[97]

Dosing and Pharmacokinetics

Raloxifene 60 mg once daily can be taken without regard for food.[97] Raloxifene is ~60% absorbed and undergoes extensive glucuronide conjugation, resulting in a 2% absolute bioavailability. Some circulating raloxifene glucuronide conjugates are converted back to the parent compound. Raloxifene and its monoglucuronide conjugates are highly protein bound. Raloxifene is primarily excreted in feces, with <0.2% excreted unchanged and <6% eliminated in urine as glucuronide conjugates. There appear to be no differences in pharmacokinetics based on age or sex. Raloxifene has a mean half-life of 27.7 hours after a single dose and 32.5 hours after multiple doses.

Adverse Effects

Adverse effects of raloxifene include an increased risk for venous thromboembolic disease, flu syndrome, headache, hot flashes, nausea, diarrhea, flatulence, gastroenteritis, leg cramps, peripheral edema, arthralgia, neuralgia, sinusitis, bronchitis, rash, sweating, and conjunctivitis.[97]

Contraindications and Potential Drug Interactions

Raloxifene carries a boxed warning and is contraindicated in patients with active venous thromboembolism or a past history of venous thromboembolism because of increased risk.[85] Raloxifene is contraindicated in females who are pregnant, plan to become pregnant, and those nursing. Raloxifene should be used with caution during periods of prolonged immobilization, in patients with a history or risk of stroke, moderate or severe renal impairment, and in patients with hepatic impairment. The coadministration of cholestyramine may decrease the absorption of raloxifene and should be avoided. Prothrombin time should be monitored when starting or discontinuing raloxifene in patients taking warfarin. Raloxifene is over 95% bound to plasma proteins and may affect highly protein-bound medications.

Bazedoxifene is a third-generation SERM and is available only in a combination product with conjugated estrogen.[100] It is indicated for the treatment of moderate-to-severe vasomotor symptoms associated with menopause, such as hot flashes, and the prevention of postmenopausal osteoporosis in females with an intact uterus. Because of the boxed warnings (endometrial cancer, cardiovascular disorders, and probable dementia) and adverse events associated with estrogen, its use is limited to the shortest duration possible. The manufacturer suggests that nonestrogen agents be considered when using the medication for the sole purpose of osteoporosis prevention. (See the section on ET.)

Treatment

CASE 110-4

QUESTION 1: T.J.'s 75-year-old grandmother, M.B., was diagnosed with osteoporosis 5 years ago when she fell and broke her distal forearm. At that time, it was noticed that she had multiple lumbar compression fractures and mild kyphosis. M.B. had lost 1.5 inches (3.81 cm) in height and was 5 feet tall and weighed 100 pounds (45.35 kg). She now has chronic back pain that is managed with acetaminophen or ibuprofen but states it occasionally makes her feel unsteady on her feet. A recent bone scan revealed significantly decreased bone mass (T-score: spine −3.6, hip −2.6, wrist −2.5). M.B. had her last menstrual period before her hysterectomy was performed 25 years ago. She took CEE 0.625 mg daily up until about 15 years ago when it was discontinued by her primary care physician. M.B. has hypertension for which she receives hydrochlorothiazide 25 mg daily and enalapril 10 mg daily, and she reports occasional acid reflux. She was prescribed alendronate 70 mg once weekly, but admits she was not good at filling it regularly, as it upsets her stomach and eventually stopped taking it. M.B. does take calcium carbonate 1200 mg/day in divided doses with meals and vitamin D 1000 IU daily, both of which were started after experiencing a fracture 5 years ago. M.B. does not smoke cigarettes, drink alcohol, or take any other nonprescription medications. She states it is difficult to exercise because of her back pain. Her mother fractured her hip at about her age.

Does M.B. exhibit any clinical signs of osteoporosis?

There are few clinical signs of osteoporosis. It is usually asymptomatic until a fracture occurs. M.B. exhibits a loss of 1.5 inches (3.81 cm) in height and mild kyphosis. She also has mild back pain. There are other causes of kyphosis, but M.B. exhibits kyphosis because of compression fractures associated with osteoporosis. (See Case 110-2, Question 1, for further information about osteoporosis clinical signs and symptoms.)

CASE 110-4, QUESTION 2: What changes, if any, should be made to M.B.'s treatment plan?

A treatment plan for M.B. should be aimed at preventing further bone loss and minimizing falls, which could lead to fractures. It is important for M.B. to continue calcium and vitamin D in her diet and maximize her physical function by incorporating exercise in her treatment plan. M.B. has experienced a previous fracture and

vertebral compression because of osteoporosis. She is at a higher risk for a subsequent fracture. The benefits of pharmacologic treatment using a different medication or reinitiating alendronate should be discussed with M.B., along with counseling on adherence.

RECURRENT FRACTURE RISK

Vertebral fractures are a common consequence of osteoporosis and are associated with a decreased health-related quality of life (HRQOL).[101],[102] They can occur without symptoms and may go unrecognized at the time of the fracture. The risk of an additional vertebral fracture within a year of the incident fracture is five times higher compared to postmenopausal females with no previous vertebral fracture.[101],[103] The physical symptoms resulting from vertebral fractures become more evident with each recurrence.[101] They are associated with loss of height, pain, decreased mobility, and mortality. The risk of recurrent fracture is also high at other sites such as the hip and wrist. A large, random cohort of almost 40,000 U.S. Medicare beneficiaries, who were not enrolled in a prescription benefit plan, were evaluated for the occurrence of a second fracture or death using data from 1999 to 2006.[104] The 5-year risk of second fracture increased with age, and the 5-year risk of death increased with age and concurrent comorbidity. Risk was greatest 6 to 24 months after the first fracture for both mortality and second fracture. The authors concluded that the risk of second fracture, which was >20% in most measured subcategories, warranted the need for prescription osteoporosis treatment.

DIETARY INTAKE

Calcium and vitamin D supplementation in combination can improve bone density and may prevent fractures in postmenopausal females with osteoporosis.[53],[55]

Sufficient dietary calcium and vitamin D are a universal recommendation for older adults with osteoporosis. Maintaining serum 25(OH)D levels above 30 ng/mL (75 nmol/L) is an important goal as low levels of vitamin D are associated with an increased risk

of falling.[1],[105],[106] The dietary goal for all patients with osteoporosis is to eat a well-balanced diet rich in fruits and vegetables, low-fat dairy products, whole grains, fish, and nuts. She should try to maintain her BMI between 20 and 25 kg/m^2. In patients like M.B., it is important to ensure vitamin D levels are adequate and dietary intake of calcium is at least 1200 mg/day. If M.B. does not achieve this from her diet, the supplements she is currently taking would be recommended. Intestinal absorption of calcium carbonate is dependent on stomach acid. There is some controversy on whether gastric acid secretion is decreased with aging and if patients who are older should take calcium citrate instead of calcium carbonate.[107],[108] Calcium carbonate supplements are the form most often associated with constipation, which can be problematic as gastric motility is decreased with aging.[107],[108] Calcium citrate should be used over calcium carbonate in patients with achlorhydria, a condition common in older adults, and in those patients who report constipation. M.B. should continue taking her calcium carbonate in divided doses with meals. If there is a question of absorption because of lower gastric acid or constipation, M.B. could switch calcium products to calcium citrate. (See Case 110-1, Questions 2 and 3, for further discussion on calcium requirements, supplementation, and product selection and the use of vitamin D.)

EXERCISE AND FALL PREVENTION

Falls are common among older adults and the leading cause of fractures and injury, both fatal and nonfatal.[109] One in three adults over age 65 years fall each year. Fall-related fractures occur more often among older females than males, although males are more likely to die from fall-related fractures than females. Pain and disability are common results of falling as well as developing a fear of falling again. Those ages 75 and older are five times more likely to be admitted to a long-term care facility than those between ages 65 and 75 years. Fall prevention that includes exercise training is an important nonpharmacologic treatment for older patients with osteoporosis. In a meta-analysis of 17 randomized controlled trials of

various fall prevention programs in community-dwelling patients over age 60 years, exercise significantly reduced the rate of falls, including falls resulting in injuries or fractures.[110] A reduction of about 37% for all injurious falls was found, along with a reduction of 43% for severe injurious falls, and 61% for falls resulting in fractures.

Exercise helps maintain bone mass, function, and agility. Older patients should be screened at least once per year for fall risk to determine if there are any underlying factors or medical conditions associated with the risk of falls.[111] Any patient who presents to a clinician after a fall should have a risk assessment as well. Patients at higher risk of falling include those with deficits in gait and balance, foot problems, impairment of vision, cardiovascular disease, postural hypotension, and vitamin D deficiency. Removal of contributing factors and treating underlying medical conditions with the fewest medications possible can reduce the risk of falling. Pharmacists have an important role in optimizing medication therapy to decrease central nervous system (CNS) effects or adverse effects affecting cognition and blood pressure. The prevention of falls also includes maintaining a safe environment; reducing tripping hazards, adding handrails inside and outside the tub or shower and next to the toilet, and improving the lighting in the home.[109,111]

Vertebral fractures can present with differing degrees of pain and disability. M.B. should include a regular weight-bearing and strengthening exercise routine that is appropriate for her age and physical condition. A referral to physical therapy may be needed to introduce M.B. to individualized exercises that will improve her strength and balance.

PHARMACOTHERAPY

Pharmacologic treatment is indicated in patients who have experienced a hip or vertebral fracture, in those with T-scores < −2.5 at the femoral neck, total hip, or lumbar spine, and in postmenopausal females and males ages 50 and older with low bone mass and high risk of fracture.[1] Agents approved for treatment of osteoporosis include bisphosphonates (alendronate, risedronate,

ibandronate, and zoledronic acid), calcitonin, denosumab, estrogen, raloxifene, and teriparatide, abaloparatide, and romosozumab. Drug therapy decisions in a patient with osteoporosis or risk of fracture should be based on the patient's medical history, patient preferences, and a balance of the risks and benefits of a medication. The goal of pharmacotherapy is to reduce the rate of fractures with the least amount of adverse effects. Head-to-head trials are often the best evidence for comparison, but this evidence is not always available. Osteoporosis diagnosis and evaluation of bone health are based on BMD assessment, which is used to estimate fracture risk. When searching for the best therapy, it is important to be mindful that the basis of treatment is the reduction of fractures. Trials reporting BMD alone may not be sufficient to predict the effect on fractures.

CASE 110-4, QUESTION 3: What medications might be considered for the treatment of osteoporosis in M.B.?

ESTROGEN

As discussed in Case 110-2, conjugated ET has positive effects on BMD and fracture rates but is no longer recommended for the treatment of osteoporosis. M.B. may have benefited from years of using ET, preserving BMD, but the benefit of ET on BMD only occurs while taking it. Bone loss is accelerated once hormone therapy is stopped, thus, M.B. and her physician should discuss another drug for the treatment of her osteoporosis.

SELECTIVE ESTROGEN-RECEPTOR MODULATORS

Raloxifene is an estrogenic agent that reduces the risk of vertebral fracture.[97] The recommended dose is 60 mg (tablet) orally once daily. It is the only SERM-approved in the United States that is indicated for the treatment and prevention of osteoporosis in postmenopausal females.

In a randomized controlled trial including almost 7000 postmenopausal females, raloxifene 60 mg or 120 mg daily for 3 years increased BMD in the femoral neck (2.1% and 2.4%,

respectively) and spine (2.6% and 2.7%, respectively) compared to placebo ($P < .001$ for all comparisons).[112] Females ages 31 to 80 were included with or without a previous vertebral fracture. The incidence of new vertebral fracture was 10.1% for placebo, 6.6% for raloxifene 60 mg/d, and 5.4% raloxifene 120 mg/d. Compared to placebo, the risk of new vertebral fracture was 0.7 (95% CI, 0.5–0.8) for raloxifene 60 mg/d and 0.5 (95% CI, 0.4–0.7) for raloxifene 120 mg/d, and risk reduction was similar regardless of preexisting fracture. There were no significant differences in total nonvertebral fractures. Serious adverse events included venous thromboembolism 0.3% for placebo and 1.0% for each 60 mg and 120 mg groups; RR 3.1 (95% CI, 1.5–6.2). Other common and significantly different adverse effects included influenza-like syndrome, hot flashes, leg cramps, and peripheral edema. Subjects enrolled in this 3-year raloxifene trial above by Ettinger et al[112] were eligible to participate in a 1-year extension with no raloxifene and then a 4-year continuation, which included raloxifene 60 mg daily for the raloxifene group.[113] The primary outcome of the 4-year extension was invasive breast cancer and included roughly 4000 females from the original trial. Raloxifene reduced the risk of ER-positive invasive breast cancer by 84% (RR 0.16, 95% CI, 0.09, 0.30). During the 1-year extension with no raloxifene, BMD decreased significantly. It increased as raloxifene was restarted and was maintained. Vertebral fracture risk was maintained 4 years after randomization but was not measured in the 4-year extension trial. BMD was measured in U.S. sites only in the 4-year extension trial and included 386 females in the final analysis.[114] After a total of 7 years on raloxifene, BMD in the femoral neck increased 1.9% from baseline and 3% from placebo ($P = .30$). BMD in the lumbar spine increased 4.3% from baseline and 2.2% from placebo ($P = .045$). The safety of raloxifene after 7 years was similar to 3 years. (See Case 110-3, Question 4, for additional information about raloxifene.)

Bisphosphonates are the major pharmacologic group of medications for the treatment of osteoporosis. A meta-analysis of seven randomized controlled trials, ~3700 participants, comparing raloxifene and alendronate was conducted to determine the efficacy

and safety of the two medications in postmenopausal females.[115] The length of the trials was at least 12 months, and the majority of trials included were of good quality. The raloxifene dose in each trial was 60 mg daily. The alendronate dose varied and included were two trials at 70 mg each week, four trials at 10 mg daily, and one trial at 5 mg daily. There were no statistical differences found between raloxifene and alendronate in the risk of vertebral fractures, nonvertebral fractures, or total fractures within a follow-up period of 12 to 24 months. There were no significant differences in upper GI disorders, venous thromboembolism, or vasodilation. There was a significantly higher rate of diarrhea found in the alendronate group and a significant increase in vasomotor events found in the raloxifene group. In a subgroup analysis, there was a higher risk of upper GI disorders for alendronate compared to raloxifene in patients over 65 years of age and for alendronate administered daily compared to raloxifene.

Raloxifene has a unique benefit and risk profile when compared to other treatments for osteoporosis. Raloxifene decreases the risk of vertebral fractures by 34% to 44% compared to placebo, but no significant differences are found in the risk of total nonvertebral fractures.[61] No differences in the rate of vertebral or nonvertebral fracture risk have been found in head-to-head trials comparing raloxifene and alendronate.[61],[115] The safety and efficacy of raloxifene has been studied in a randomized controlled trial up to 7 years. Significant adverse effects include an increase in venous thromboembolism; myalgias, cramps, and limb pain; and hot flashes. The FDA has issued a boxed warning regarding the increased risk of DVT and PE while taking raloxifene and a warning of increased risk of death because of stroke in postmenopausal females with documented CHD or those at increased risk for coronary events.[97] As with other ET, it is necessary to continue raloxifene therapy to maintain increases in BMD.

Because raloxifene has not been shown to prevent nonvertebral fractures, it is not the best treatment for many patients with osteoporosis. M.B. has a high fracture risk, and other treatment options should be discussed.

Bisphosphonates

Bisphosphonates, such as alendronate, risedronate, ibandronate, or zoledronic acid, can be used as an alternative to raloxifene to prevent fractures because of osteoporosis. All bisphosphonates are effective in reducing vertebral fracture and have similar efficacy.[76] Only alendronate, risedronate, and zoledronic acid reduced nonvertebral fractures. The choice of bisphosphonate as well as monitoring to ensure the medication is taken as directed can affect their clinical benefit. No statistical differences are seen between agents, but poor adherence will decrease their fracture benefit (see Case 110-5, Question 4).

M.B. has been diagnosed with osteoporosis, and her risk of fall and recurrent fracture is high. Oral alendronate was not tolerated, and risedronate has a similar GI adverse effect profile. Oral bisphosphonates, as previously prescribed, may not be the best choice for M.B. Injectable agents are appropriate for patients at high fracture risk. Zoledronic acid may be slightly more potent in preventing vertebral fracture, is effective in reducing hip fracture, and is administered only once per year. It is less likely to cause GI symptoms than oral bisphosphonates but has its own adverse effect profile to be discussed with the patient and should not be administered in patients with an estimated creatinine clearance <35 mL/minute.

Case 110-4, Question 4: What other possible alternatives or additive therapies for the treatment of postmenopausal osteoporosis are available for M.B.?

Calcitonin

Calcitonin decreases bone resorption and bone turnover.[116] Synthetic calcitonin made from salmon is 40 to 50 times more potent than human calcitonin. Calcitonin inhibits osteoclasts and renal excretion of calcium. Because of its mechanism of action, calcitonin decreases both total serum calcium and serum ionized calcium. All patients receiving calcitonin should supplement with at least 1000 mg of

calcium per day and at least 400 IU of vitamin D per day. A nasal spray and an injectable formulation are available and indicated for the treatment of osteoporosis in females who have been postmenopausal for at least 5 years.[117],[118] Injectable calcitonin is also indicated for the treatment of hypercalcemia and Paget disease. Calcitonin is only recommended for the treatment of osteoporosis when alternatives are not suitable and can be considered third-line treatment.[25],[32],[117] Fracture reduction has not been demonstrated for either formulation in quality clinical trials.

Common nasal symptoms from nasal administration include rhinitis, nasal sores, irritation, itching, sinusitis, and epistaxis.[118] Local skin reactions (10%) are common with injectable calcitonin.[117] Nausea with or without vomiting (10%) and flushing (2%–5%) can occur at the initiation of therapy, but subsides over time. Other adverse effects include arthralgia, headache, and back pain. More severe adverse effects associated with calcitonin salmon include serious hypersensitivity, hypocalcemia, and malignancy. Injectable calcitonin should be refrigerated when not in use and nasal spray refrigerated until it is opened for use; thereafter, it is stable for 35 days at room temperature. Calcitonin nasal spray should be used in alternate nostrils daily. Because of calcitonin salmon's weak efficacy, alternative treatments should be used for the treatment of osteoporosis.

The nasal spray and injectable formulation of calcitonin have been used short term to reduce pain because of vertebral fracture.[23] Calcitonin has an analgesic effect and may be beneficial short term to reduce pain score after acute vertebral fracture. A meta-analysis conducted to assess the analgesic effect of calcitonin included 10 studies that involved adults aged 60 years and older who suffered from acute (onset < 10 days) or chronic back pain (>3 months).[119] Intervention groups received nasal spray, injection, or suppository. After 1 week, there was a significant reduction in acute pain at rest and acute pain while walking and was sustained until the end of the treatment period of 4 weeks. There was no difference in chronic pain at rest. There was no difference in chronic pain with activity at 1 month, 3 months, or 1 year, but a slight reduction at 6 months. The

authors state the review supports the use of calcitonin for the acute but not chronic pain of osteoporotic vertebral compression fracture.

A short-term prescription of calcitonin is recommended if M.B. suffers from acute pain from a new vertebral fracture.

Denosumab

Denosumab is a human monoclonal antibody that binds to RANKL, a regulator of bone-resorbing osteoclasts.[20] Denosumab is administered by subcutaneous injection every 6 months and inhibits bone turnover with a rapid onset. Denosumab significantly increases BMD in the lumbar spine, total hip, and at the femoral neck compared to placebo.[120] This effect dissipates quickly, and BMD returns to approximately baseline levels within 12 months of discontinuation.

In a large randomized, placebo-controlled, multicenter trial that included 7868 postmenopausal females with osteoporosis, denosumab 60 mg subcutaneously every 6 months was compared to placebo for a duration of 36 months.[121] Denosumab reduced the primary outcome of new clinical vertebral fracture, 2.3% versus 7.2% (RR 0.32; 95% CI, 0.26–0.41; $P < .001$). Denosumab slightly reduced the cumulative risk of new hip fracture, 0.7% versus 1.2% (HR, 0.60; 95% CI, 0.37–0.97; $P = .04$), and also reduced the cumulative risk of nonvertebral fracture, 6.5% versus 8.0% (HR 0.80; 95% CI, 0.67–0.95; $P = .01$). Eczema occurred in 3% of patients receiving denosumab and 1.7% for placebo ($P < .001$). A serious skin infection occurred in 12 patients (0.3%) receiving denosumab and only 1 patient receiving placebo ($P = .002$). Other adverse effects were similar in both groups.

In two head-to-head clinical trials comparing denosumab to weekly alendronate, denosumab was associated with greater increases in BMD at the hip, lumbar spine, femoral neck, and radius at 12 months.[122],[123] Similar findings have been published comparing denosumab to monthly ibandronate.[124] At 12 months, BMD was significantly higher at the total hip, femoral neck, and lumbar spine in postmenopausal females receiving denosumab than in those

receiving ibandronate. Palacios et al pooled data from two trials comparing denosumab 60 mg subcutaneously every 6 months to either ibandronate or risedronate, 150 mg once monthly for 12 months.[125] Postmenopausal females with low BMD and suboptimal adherence with prior oral bisphosphonate therapy were included in the trials. A treatment satisfaction questionnaire at baseline was compared to 6 and 12 months. Satisfaction improved in all patients but was significantly higher in the denosumab group ($P < .001$). Qualitative measures of effectiveness, side effects, convenience, and overall satisfaction were greater in patients who transitioned to denosumab. The clinical outcome of fracture was not reported, and the comparison of fracture risk between denosumab and oral bisphosphonates cannot be made.

Denosumab is approved for the treatment of postmenopausal females with osteoporosis who are at high risk for fracture.[120] Common adverse reactions include back pain, pain in extremity, hypercholesterolemia, musculoskeletal pain, and cystitis. Serious infections including cellulitis can occur when taking denosumab as well as skin rash and eczema. There is a risk of hypocalcemia with treatment. Adequate supplementation of calcium and vitamin D, at least 1000 mg of calcium and 400 IU of vitamin D daily, is recommended. Hypocalcemia must be corrected before the initiation of treatment. Serious hypersensitivity reactions, pancreatitis, osteonecrosis of the jaw (ONJ), and atypical femur fractures have all been reported. Denosumab is available as prefilled syringes that should be stored in the refrigerator at 36 to 46 °F (2–8 °C). It should be left out for 15 to 30 minutes and brought to room temperature for administration. It is recommended that a health care provider administers denosumab by subcutaneous injection in the upper arm, upper thigh, or abdomen.

Duration of denosumab has been studied up to 10 years with good safety, and recent treatment guidelines do not recommend drug holidays for denosumab.[23] Denosumab is a good option for M.B. Denosumab does not require a dose adjustment for renal insufficiency, but it is recommended by the manufacturer that

calcium, phosphorus, and magnesium be monitored in patients with an estimated creatinine clearance <30 mL/minute.[120]

Parathyroid hormone

Endogenous PTH regulates the level of calcium in the blood.[31] Even a small decrease in calcium will cause secretion of PTH. It acts on the kidneys to conserve calcium and stimulate the production of calcitriol, which increases the absorption of calcium. PTH stimulates bone formation and bone resorption, but also increases the movement of calcium from the bone to the blood. Hyperparathyroidism is uncontrolled overactivity and the continuous secretion of PTH. Excessive PTH causes bone breakdown by osteoclasts and has been shown to contribute to bone loss and bone fragility. A controlled intermittent injection, however, promotes bone formation, increasing BMD and bone size. Teriparatide is a human recombinant fragment of the first 34 amino acids of PTH (PTH 1-34), which produce most of its chief biologic effects.[126] It is available as a multidose pen and given as a daily 20 µg subcutaneous injection. Abaloparatide is a human parathyroid hormone–related peptide [PTHrP(1-34)] analog.

It is also available as a multidose pen and given as a daily 80 µg subcutaneous injection. Both are approved for the treatment of postmenopausal females and males with osteoporosis who are at high risk for fracture.

Early clinical trials in humans were stopped prematurely because animal data showed an increased incidence of osteosarcoma at high doses and long duration.[31],[126] A boxed warning for the potential risk of osteosarcoma appears in the manufacturer's package information for both medications, and dispensing of a medication guide is required with each new or renewed prescription.

Abaloparatide and teriparatide significantly increase BMD and decrease the risk of vertebral and nonvertebral fractures compared to placebo.[80],[127–129] ACTIVE was the phase 3 clinical trial of abaloparatide that included a 1:1:1 design compared to placebo and teriparatide.[80] Both abaloparatide and teriparatide were significantly

more effective than placebo in improving BMD and reducing fracture risk. There were no significant differences in the reduction of nonvertebral fracture when abaloparatide was compared to teriparatide (HR 0.79, 95% CI, 0.43–1.45). Increases in BMD for abaloparatide were significantly greater than teriparatide at the total hip and femoral neck at 6, 12, and 18 months ($P < .001$) and at lumbar spine at 6 and 12 months ($P < .001$). Discontinuation because of adverse effects was higher in the abaloparatide group (9.9%) compared to teriparatide (6.8%) or placebo (6.1%) and because of nausea, dizziness, headache, and palpitations. Hypercalcemia occurred more frequently in the teriparatide group (12.5% vs 11.3%). Palpitations occurred more frequently in the abaloparatide group (5.1% vs 1.6%). Serious adverse effects were similar between abaloparatide and teriparatide. Adverse effects are usually mild and transient.[23] Common adverse effects are hypercalciuria, dizziness, nausea, headache, and orthostatic hypotension.[23],[126],[130] No dosage adjustments are required in patients with renal insufficiency.

Teriparatide and abaloparatide have unique mechanisms of action that make it attractive to combine them with other medications to treat osteoporosis. As it was approved more recently than teriparatide, there are yet no studies of abaloparatide in combination with other medications.

Teriparatide has been given safely in combination with denosumab for 12 months along with a 12-month extension in a small trial ($N = 94$) of postmenopausal females.[131],[132] At 12 months, all groups had a significant change in BMD, but the combination resulted in greater increases in BMD than with either medication alone. At 24 months, BMD continued to increase, but the increase in hip and femoral neck BMD from teriparatide was significantly higher than in the first year and when compared to the second 12 months of denosumab. Overall, increases in BMD at the femoral neck (6.8%), total hip (6.3%), and spine (12.9%) are greater from the combination of teriparatide and denosumab than can be achieved from either drug alone. BMD of the distal radius increased at 24 months, but a decrease in BMD from baseline occurred in the teriparatide group.

Medications were well tolerated. Mild hypercalcemia was reported in the first 12 months but did not occur in the second 12 months. Serious adverse effects were reported, but all were judged unrelated to the medications.

In a small study, teriparatide was given to patients previously on alendronate or raloxifene as add-on therapy and compared to patients who switched to teriparatide alone.[133] At 18 months, BMD increased in all groups at the lumbar spine compared to baseline. However, the addition of teriparatide to alendronate or raloxifene in females on long-term therapy instead of switching to teriparatide alone resulted in significantly increased BMD at the total hip and femoral neck. In treatment-naive patients, a single dose of zoledronic acid 5 mg plus daily teriparatide 20 µg was compared to zoledronic acid alone or daily teriparatide alone. At 1 year, BMD in the lumbar spine improved significantly in the combination group compared to zoledronic acid alone, but was not different than teriparatide alone.[134] BMD in the total hip was increased in the combination group and significantly different from teriparatide alone, but not different from zoledronic acid alone.

Teriparatide has been used to treat and promote the healing of bisphosphonate or denosumab-induced osteonecrosis of the jaw.[135],[136] Weekly administration at different doses are being explored for the prevention of vertebral fractures.[137],[138]

Abaloparatide for 18 months was followed by alendronate 70 mg weekly in the ACTIVE extension trial.[139] The abaloparatide group and the placebo group from ACTIVE each received alendronate 70 mg weekly for 24 months (ABL/ALN vs PBO/ALN). In the 24-month period, the difference in radiographically determined vertebral compression fractures was significantly better for ABL/ALN (*N* = 2 [0.37%]) than PBO/ALN (*N* = 16 [2.82%]), *P* = .001. After 24 months, no significant difference was found for nonvertebral, clinical, and major osteoporotic fractures. When considering the entire study period of 43 months (ACTIVE and ACTIVE extension), the benefits of treatment with abaloparatide versus placebo were sustained after 24 months of alendronate 70 mg weekly and a significant difference

remained between groups for vertebral, nonvertebral, clinical, and major osteoporotic fractures.

Initial administration of teriparatide and abaloparatide should be given when the patient can sit or lie down as orthostatic hypotension may occur with the initial doses.[126],[130] Orthostatic hypotension may occur within 4 hours of administration and spontaneously resolves after a few minutes to hours for the first several doses. Patients should immediately sit or lie down if symptoms occur. Teriparatide should always be stored under refrigeration at 36 to 46 °F (2–8 °C) and injected immediately on removal from refrigeration. Time outside of the refrigerator should be minimized. After use, the pen should be recapped and protected from light and discarded after 28 days. Abaloparatide should be stored under refrigeration at 36 to 46 °F (2–8 °C) until use. After the first dose, it can be stored at room temperature 68 to 77 °F (20–25 °C) for up to 30 days. Doses should only be administered subcutaneously and not intramuscularly (IM) or IV.

Romosozumab

Romosozumab is a monoclonal antibody and sclerostin inhibitor indicated for the treatment of osteoporosis in postmenopausal females at high risk for fracture.[140] Romosozumab is administered by a health care provider as two separate subcutaneous injections (105 mg/1.17 mL single-use prefilled syringe), one after the other, for a total dose of 210 mg. Sclerostin is a glycoprotein encoded by the *SOST* gene and secreted by osteocytes, which inhibits bone formation.[21],[141] Romosozumab inhibits the effect of sclerostin by stimulating osteoblastic activity and results in increased bone formation and decreased bone resorption, improving bone structure and strength.[140] Romosozumab is administered monthly for 12 months.

In a large clinical trial that included 7180 postmenopausal females with T-score of −2.5 to −3.5, monthly romosozumab was compared to matching placebo.[142] After 12 months, both groups received denosumab every 6 months for 12 months. Average age of patients

was 70.9 years. At 12 months, new vertebral fracture occurred in 0.5% in the romosozumab group and 1.8% in the placebo group, RR 0.27 (95% CI, 0.16–0.47). Clinical fractures occurred in 1.6% in the romosozumab group and 2.5% in the placebo group, HR 0.64 (95% CI, 0.46–0.89). Nonvertebral fractures occurred in 1.6% in the romosozumab group and 2.1% in the placebo group, HR 0.75 (95% CI, 0.53–1.05). At 24 months, after 12 months of denosumab, new vertebral fracture remained significantly lower (0.6% vs 2.5%, $P < .001$). Clinical fractures and nonvertebral fractures were lower in the romosozumab group, but the difference was not considered significant. At 12 months, romosozumab increased BMD by 13.3% at the total hip, 6.9% at the lumbar spine, and 5.9% at the femoral neck. Adverse effects were similar between romosozumab and placebo; hypersensitivity occurred in seven patients in the romosozumab group, and two instances of ONJ occurred after 12 months in the romosozumab group after denture fitting and tooth extraction procedures.

In a small phase 2 dosing study that included postmenopausal females with a T-score between −2.0 and −3.5, five different doses of romosozumab were compared to open-label oral alendronate (ALN) 70 mg weekly ($N = 47$) or teriparatide (TPTD) 20 μg subcutaneously (SC) once daily ($N = 46$).[143] Romosozumab 210 mg monthly for 12 months ($N = 49$) had significantly higher BMD gains at the lumbar spine (11.3%, 4.1%, 7.1%), total hip (4.1%, 1.9%, 1.3%), and femoral neck (3.7%, 1.2% 1.1%) than ALN or TPTD, respectively. No significant difference was found at the third of the radius.

Romosozumab is approved for the treatment of osteoporosis in postmenopausal females at high risk, but has been studied in males with positive results and significant improvement of BMD at the lumbar spine and total hip compared to placebo.[144]

Romosozumab should be administered in the abdomen, thigh, or upper arm by a health care provider as two separate subcutaneous injections, one after the other, to total 210 mg.[140] It should be stored under refrigeration at 36 to 46 °F (2–8 °C) until use and allowed to sit at room temperature for at least 30 minutes before administration.

Injection sites should be rotated. Serious cardiovascular risk was seen in phase 3 clinical trials warranting a boxed warning. The manufacturer states that romosozumab should not be initiated in patients who have had a myocardial infarction or stroke within the preceding year because of the risks of myocardial infarction, stroke, and cardiovascular death.

Patients should continue to take adequate supplements of calcium and vitamin D during treatment. Arthralgia and headache are the most common adverse reactions, arthralgia being the most common problem that leads to discontinuation of treatment. Adverse effects also include injection-site reaction, hypersensitivity, hypocalcemia, ONJ, and atypical fracture. No dosage adjustments are required in patients with renal insufficiency, but the manufacturer recommends monitoring for hypocalcemia in patients with eGFR <30 mL/minute/1.73 m^2.

Injectable agents are considered for patients at high fracture risk like M.B. The goals of the therapy are to prevent fracture, improve strength, and prevent falls, and multiple options are available to help achieve these goals. Teriparatide, abaloparatide, and romosozumab are considered anabolic agents, which increase bone formation. Duration of administration is limited to 1 year for romosozumab and 2 years for PTH analogs. Duration of zoledronic acid should be assessed after 5 years, and duration with denosumab has been studied for up to 10 years. There are administration differences between agents: monthly versus biannually versus yearly. Denosumab and romosozumab, along with bisphosphonates, have been associated with ONJ and atypical fractures. Romosozumab has additional warnings of potential cardiovascular risk where PTH analogs have additional warnings of osteosarcoma. Risks should be communicated to patients, and decisions regarding appropriate therapy for patients like M.B. should be based on comorbidities, medical history, ease of administration or access for the patient, adverse effects, duration of treatment, and cost.

Glucocorticoid-Induced Osteoporosis

CASE 110-5

QUESTION 1: D.J. is a 56-year-old male who was diagnosed with Crohn disease 10 years ago. D.J. has been somewhat stable on methotrexate and sulfasalazine for the past 5 years. D.J. has experienced increased symptoms for the past week, which have been getting progressively worse. D.J. was hospitalized and started on parenteral corticosteroids and discharged on 60 mg/day of prednisone to slowly taper over 3 months. Because this is the third flare of his disease in 2 years, D.J.'s physician was concerned about the risk of osteoporosis. As a member of the health care team, you will meet with D.J. at his follow-up visit in a few days. During your meeting with D.J., he asks you why males have to worry about osteoporosis.

What explanation can you provide to D.J., including his risks, and outline patient-specific goals?

Systemic glucocorticoid therapy, such as prednisone, is one of the most common causes of secondary osteoporosis.[145] The risk of fracture increases at the start of therapy, is highest within 3 to 6 months, and decreases after discontinuation.[146] Fracture risk increases with increased dose and duration of therapy and is influenced by patient-specific risk factors such as low body mass, family history, age, race, or sex (see Case 110-1, Risk Factors). Glucocorticoids contribute to bone loss resulting in osteoporosis by reducing the life span of osteoblasts, increasing osteocyte apoptosis, decreasing the production of osteoprotegerin, and inhibiting estrogens and androgens. Glucocorticoids both reduce bone formation and increase bone resorption.

D.J. is at risk for substantial loss of bone mass because of a high dose of prednisone for an extended period of time. The goal while he is on glucocorticoid therapy would be to minimize bone loss. D.J. would be a candidate for pharmacologic therapy for the prevention of osteoporosis while taking prednisone. The minimum threshold for risk of osteoporosis according to NOF is 5 mg prednisone or equivalent daily for 3 months.[1] The NOF recommends BMD testing in adults with a condition such as rheumatoid arthritis, or those meeting this glucocorticoid threshold.

CASE 110-5, QUESTION 2: What medications are available to prevent osteoporosis-related fractures in D.J.?

Alendronate, risedronate, zoledronic acid, denosumab, and teriparatide are FDA approved for the treatment of glucocorticoid-induced osteoporosis (GIOP). The American College of Rheumatology (ACR) guidelines for the prevention and treatment of GIOP recommend optimal calcium and vitamin D intake and a lifestyle that includes a balanced diet, weight-bearing exercise, reduced alcohol intake, and smoking cessation.[146] All patients taking >2.5 mg/day for >3 months of prednisone or equivalent should be assessed for fall and fracture risk that includes using FRAX® for adults age 40 years and older. Treatment is recommended for patients who are at moderate and high risk of fracture. High-risk patients are those with a T-score of −2.5 or lower or FRAX® 10-year fracture risk of ≥20% (spine, hip, shoulder, wrist) or risk of ≥3% (hip) or those who are age 40 years and younger with a prior osteoporotic fracture. Moderate-risk patients include those with a T-score of −2.5 or lower or FRAX® 10-year fracture risk of 10% to 19% (spine, hip, shoulder, wrist) or risk of 1% to <3% (hip) or those who are age 40 years and younger with a Z-score < −3 or those continuing on glucocorticoid therapy ≥7.5 mg/day for ≥6 months.

Oral bisphosphonates are preferred and then zoledronic acid, teriparatide, or denosumab if oral agents are not tolerated. ACR suggests that raloxifene can be used for postmenopausal females if other medications are not appropriate.

BISPHOSPHONATES

A Cochrane systematic review was conducted to evaluate the benefits and risks of bisphosphonates for the prevention and treatment of GIOP in adults.[147] A total of 27 randomized controlled trials were included that addressed the prevention or treatment of GIOP in adults taking a mean steroid dose of ≥5.0 mg/day. Bisphosphonates significantly increased BMD of the lumbar spine (3.5%) and femoral neck (2.06%) and significantly reduced the risk

of vertebral fracture, RR 0.57 (95% CI, 0.35–0.91). Bisphosphonates resulted in fewer nonvertebral fractures, but results were not statistically significant. There was no significant difference of serious adverse effects for bisphosphonates compared to the control group.

When comparing oral bisphosphonates to IV zoledronic acid, two studies found that increases in BMD in the lumbar spine were significantly greater for zoledronic acid compared to risedronate 5 mg daily.[148,149]

Although daily doses of alendronate and risedronate are approved for the indication of GIOP, weekly doses are more frequently used in clinical practice and significantly reduce the incidence of fracture.[150] Weekly doses also improve adherence (see Case 110-5, Question 4: Adherence).

DENOSUMAB

Denosumab was assessed in the treatment of GIOP in a phase 3 study in two subpopulations.[151] Adults 18 years old and older who had received ≥7.5 mg daily prednisone or equivalent for either <3 months (glucocorticoid-initiating) or for ≥3 months (glucocorticoid-continuing) were included. Denosumab 60 mg SC every 6 months was compared to risedronate 5 mg PO daily for 24 months. Only 74.2% of the 290 glucocorticoid-initiating patients and 505 glucocorticoid-continuing patients completed the trial. After 24 months, denosumab significantly increased BMD compared to risedronate at the lumbar spine, total hip, femoral neck, and third of the radius; glucocorticoid-initiating population (4.5%, 3.1%, 2.5%, 1.5%) and glucocorticoid-continuing (3.2%, 2.5%, 1.8%, 1.6%), respectively. Fractures were reported in 8% of patients in the denosumab group and 9.1% in the risedronate and were not statistically different. Adverse events were similar for both interventions, but serious infection occurred in four patients taking risedronate, and atypical femoral fracture occurred in one patient in the denosumab group.

PARATHYROID HORMONE

Teriparatide is also approved for the treatment GIOP. A 36-month trial conducted by Saag et al compared teriparatide 20 µg subcutaneously daily versus alendronate 10 mg oral daily.[152] The study included 400 males and females, primarily with rheumatologic conditions. Teriparatide increased spinal BMD 7.2% versus 3.4% in the alendronate group after 18 months of therapy. Hip BMD increased 3.8% in the teriparatide group versus 2.4% in the alendronate group. Differences between groups were noted as early as 6 months. At 36 months, teriparatide continued to increase BMD in the spine, hip, and femoral neck to a greater extent than alendronate. There were fewer vertebral fractures in the teriparatide group (1.7%) than in the alendronate group (7.7%; *P* = .007). No significant difference in nonvertebral fractures was found between groups. A small (*N* = 95), 18-month trial compared teriparatide 20 µg subcutaneously daily to risedronate 35 mg weekly in males with a minimum of 3 months prior glucocorticoid use (median 6.4 years).[153] Significant increases in BMD from baseline were found in both treatment groups, but a significantly greater increase occurred with teriparatide (16.3% vs 3.8%; *P* = .004). No vertebral fractures occurred during the trial. A total of five patients in the risedronate group (10.6%) developed new clinical fractures, whereas no fractures occurred in the teriparatide group (*P* = .056).

Case 110-5, Question 3: What recommendations should D.J.'s clinician share with him for preventing osteoporosis?

Adequate dietary calcium and vitamin D are essential. Supplementation is recommended if needed to maintain dietary calcium 1000 to 1200 mg daily and vitamin D 800 to 1000 IU daily.[146] Lifestyle changes are encouraged in patients and include smoking cessation, reduced alcohol intake, and regular exercise.

BMD testing is recommended for D.J. as well as fracture risk assessment using FRAX®. If found at moderate to high risk of fracture, D.J. would be a candidate for bisphosphonate therapy. He could receive an oral bisphosphonate such as alendronate 70 mg

weekly or risedronate 35 mg weekly while taking prednisone. He should be counseled on the proper administration and adverse effects of bisphosphonates and receive a medication guide with the medication. (See Case 110-3, Question 2.)

D.J. should choose one day of the week he will remember to take his medication. It should be taken in the morning on an empty stomach with a full glass of water. He should remain upright and not eat or drink anything for at least 30 minutes after taking his dose.

CASE 110-5, QUESTION 4: How does adherence affect prevention or treatment of osteoporosis?

Osteoporosis is a major public health concern but is an asymptomatic disease until fracture occurs. Although many medications used to treat osteoporosis have the convenience of less frequent dosing, adherence is not optimal.[61] Potential barriers to adherence of osteoporosis medication include dosing frequency, side effects of medications, comorbid conditions, knowledge about osteoporosis, and cost.

Adherence in clinical trials does not typically reflect real-world patients. Of 18 randomized controlled trials that reported rates of adherence, the majority reported over 90%. Of 59 observational studies, adherence was substantially lower: 10 of 13 adherence studies reported rates below 50%; in studies using data from health plans, 35% to 52% of patients had an adherence rate of 80% or above; and in several marketing scans adherence above 80% ranged from 23% to 49%, and only 33.5% for teriparatide.

In a meta-analysis of bisphosphonate adherence including 15 observational studies (*N* = 704,134), the overall risk of fracture was estimated to be 46% higher when low adherence was compared to high adherence.[154] This meta-analysis was limited by heterogeneity and differences in the observational study designs.

A systematic review that included two separate searches of male osteoporosis included 18 studies related to adherence and 37 studies related to cost.[155] This systematic review also included

mostly observational studies and did not pool the data. Over a 1-year period, only 32% to 64% of males were above 80% adherent to the medication above. Overall, clinical outcomes were worse with nonadherence. The overall cost associated with osteoporotic fractures in males is not as high as in females, but four studies that explored direct and indirect costs found the overall cost per fracture in males is higher than in females.

A systematic review of 89 observational studies was conducted to summarize patient adherence and persistence to oral bisphosphonates for the treatment of osteoporosis.[156] For males and females, adherence and persistence decrease over time. Adherence at 1 year ranged from 31.7% to 72%, at 2 years 34.5% to 47.9%, and at 3 years 23% to 47.9%. Persistence was reported as the length of treatment without a gap in refills. The average persistence of oral bisphosphonates at 6 months ranged between 34.8% and 71.3%, at 1 year 17.65% and 74.8%, 2 years 12.9% and 60.6%, and 3 years, 21% and 40%. Weekly oral bisphosphonates users were found to have a significantly higher mean persistence than those who took medication daily. Persistence and adherence may be related to patient characteristics such as age, socioeconomic status, comorbidities, and concomitant medication such as glucocorticoids.

Oral bisphosphonates are first-line agents for the prevention and treatment of osteoporosis. Weekly doses improve adherence compared to daily doses; monthly doses do not improve adherence compared to weekly doses, and monthly adherence may be slightly lower.[157-159]

Although the consequence of poor adherence is an estimate, it makes sense that promoting adherence will improve the effect of bisphosphonates and is important to achieve the results that are reported in clinical trials.

OSTEOPOROSIS IN MALES

CASE 110-6

Question 1: M.B.'s husband, J.B., is 77 years old and presents to his physician for a routine physical examination. J.B.'s wife has osteoporosis, and his daughter has low bone mass. J.B. would like to know if males develop osteoporosis.

Should he be tested for osteoporosis?

The NOF estimates that ~10 million Americans have osteoporosis and that 2 million are males.[1,160] An additional 12 million males are at risk for osteoporosis. The prevalence in males increases later in life, with the greatest increase seen at age 80.[161] The age-adjusted prevalence of osteoporosis at either the femoral neck or lumbar spine differs by race (4% non-Hispanic White males; 9% other races) as does the prevalence of low bone mass (24% non-Hispanic Black males; 39% non-Hispanic White males). Approximately 80,000 males will break a hip each year, and mortality rates after hip fracture are higher in males than in females.[160]

In an Endocrine Society Clinical Practice Guideline for Osteoporosis in Men, Watts et al[24] suggest BMD testing for all males age 70 and older; males with a history of fracture after age 50; and in males age 50 to 69 with conditions or disease states such as delayed puberty, alcohol abuse, smoking, hypogonadism, hyperparathyroidism, hyperthyroidism, chronic obstructive pulmonary disease (COPD), and glucocorticoid or gonadotropin hormone–releasing hormone (GnRH) agonists use.

J.B. is over age 70 and should have a DEXA of the spine and hip to measure BMD.[1,24] When a spine or hip BMD is not possible and in males receiving androgen-deprivation therapy (ADT) or with hyperparathyroidism, a DEXA of the forearm may be measured.

The same WHO criteria that was established for females is used to diagnose osteoporosis in males (T-score ≤ −2.5).[1]

Case 110-6, Question 2: J.B. knows that BMD loss in both his wife and daughter has been attributed to a decrease in hormones. Is hormone loss the same cause of osteoporosis in males?

Many risk factors contribute to osteoporosis in males (Table 110-1); however, a decrease in androgen and estrogen production are the primary hormonal contributors to the development of osteoporosis in this population.[162]

Androgens and Estrogens

Androgen production, specifically, serum testosterone concentrations, decreases with age. These decreased concentrations are thought to decrease bone formation and increase resorption. Testosterone has been linked to decreases in BMD, whereas dihydrotestosterone has not been linked.[163] Despite testosterone's importance for skeletal health in males, research now suggests that estrogen may play a more important role in skeletal biology. Two genes, ER-α and aromatase, are required for estrogen effects; ER-α is found on osteoblasts, osteoclasts, and stem cells in bone. Aromatase is present in osteoblasts and stem cells in bone. The absence of these genes results in an inability to convert androgen into estrogen. Replacement of estrogen in aromatase deficiency showed significant increases in bone mass and markers of bone turnover normalized.

Case 110-6, Question 3: Should J.B. be given supplementation for hypogonadism if his testosterone levels are low?

Hypogonadism may be a major contributor of bone loss in adult males and may increase the risk of fracture.[164] If a complete history and physical suggests a specific cause for osteoporosis, it would be appropriate for J.B.'s provider to order more tests including serum testosterone levels and replace testosterone if indicated, along with treatment for osteoporosis.[24]

Case 110-6, Question 4: If it is determined that J.B. has osteoporosis, should he receive calcium and vitamin D?

All males who are at risk for osteoporosis such as J.B. or who have osteoporosis should receive 1000 to 1200 mg of calcium daily through their diet and supplementation if necessary.[24] A 25(OH)D level should be drawn and, if indicated, J.B. should receive vitamin D to achieve a level of at least 30 ng/mL.

Case 110-6, Question 5: What therapies are available to treat osteoporosis in males?

Alendronate, risedronate, zoledronic acid, teriparatide, and denosumab are approved for the treatment of osteoporosis in males (Table 110-8). Romosozumab has been studied in males with osteoporosis in a phase 3 clinical trial.[144]

In a 2-year double-blind trial, 241 males with osteoporosis were randomized to receive either alendronate 10 mg daily or placebo.[165] One-third of the population had low serum-free testosterone levels. BMD increased by 7.1% versus 1.8% in the lumbar spine, 2.5% versus −0.1% in the femoral neck, and 2% versus 0.4% in the total body for alendronate and placebo groups, respectively. The incidence of new vertebral fractures was less in the alendronate group (0.8%) when compared with placebo (7.1%), and a smaller decrease in height was observed in the alendronate group (0.6 mm) as compared to placebo (2.4 mm).

In a 2-year double-blind, placebo-controlled trial, 284 males were randomly assigned in a 2:1 fashion to receive risedronate 35 mg weekly or placebo.[166] All patients received calcium and vitamin D supplementation. Lumbar spine BMD increased 4.5% over placebo in the risedronate group. There were no differences between groups in vertebral and nonvertebral fractures, but bone turnover markers were significantly lower in the risedronate group.

In a multicenter, double-blind, active-controlled, parallel-group study of osteoporosis, 302 males ages 25 to 85 were randomly assigned to receive once-yearly zoledronic acid 5 mg IV infusion or oral alendronate 70 mg weekly and followed for 2 years.[167] All patients received calcium and vitamin D supplementation. The

results of the study confirmed noninferiority of zoledronic acid to alendronate with similar BMD response and suppression of bone turnover markers. BMD at the lumbar spine increased by 6.1% in the zoledronic acid group versus 6.2% in the alendronate group with other sites showing similar BMD increases between groups.

Orwoll et al also conducted a multicenter, randomized, double-blind, active-controlled trial in 437 males ages 30 to 85 with BMD <2 SD lower than the young adult male mean BMD.[168] Patients received teriparatide 20 μg subcutaneously daily, 40 μg subcutaneously daily, or placebo with calcium and vitamin D supplementation for a median duration of 11 months. Lumbar spine BMD increases were noted after 3 months with increases of 5.9% in the 20-μg group and 9.0% in the 40-μg group by study end. Increases were also seen in bone turnover markers in the 20-μg and 40-μg groups. The study was originally planned to be a 2-year study, but it was stopped early after findings of osteosarcomas in rats during routine testing.

A randomized controlled trial was conducted in males ages 55 to 90 years with a T-score ≤ −2.5, or a T-score of ≤ −1.5 with fragility fracture, to determine the safety and efficacy of romosozumab.[144] A total of 245 patients with a mean age of 72 years received either romosozumab 210 mg SC monthly or matching placebo along with 500 to 1000 mg of calcium and 600 to 800 IU of vitamin D daily. After 12 months, BMD was significantly higher in the romosozumab group compared to placebo; 12.1% versus 1.2%; $P < .001$ in the lumbar spine, 2.5% versus −0.5%; $P < .001$ in the total hip, and femoral neck 2.2% versus −0.2%; $P < .001$. Fractures occurred in 1.8% in the romosozumab group and 2.5% in the placebo group. Injection-site reactions were greater in the romosozumab group than placebo, 5.5% versus 3.7%, respectively. Cardiovascular serious adverse events were greater in the romosozumab group than placebo 4.9% versus 2.5%, respectively. One cardiovascular death occurred in each group within 12 months, and one additional death occurred in the romosozumab group in the 3-month follow-up treatment.

Fewer studies are conducted in males with osteoporosis, but meta-analyses confirm positive effects from antiresorptive and anabolic medication compared to placebo in males with

osteoporosis.[169],[170] More research is needed on vertebral and nonvertebral fractures as a primary end point in studies that include males.

Case 110-6, Question 6: When is pharmacologic treatment recommended?

Pharmacologic therapy is indicated in males who are diagnosed with osteoporosis, have low bone mass in addition to a 10-year risk of hip fracture ≥3% using FRAX®, have had a hip or vertebral fracture without major trauma, and those who are on long-term glucocorticoid therapy (>7.5 mg/day of prednisone or equivalent).[24]

The Endocrine Society recommends monitoring DEXA at the spine and hip every 1 to 2 years to evaluate treatment and bone turnover markers at 3 to 6 months after starting therapy.

J.B. should maintain adequate dietary calcium and vitamin D intake. Supplementation is recommended if needed to maintain dietary calcium 1200 mg daily and vitamin D 600 IU. Lifestyle changes are encouraged in patients and include smoking cessation, reduced alcohol intake, and regular exercise.

Drug Index

Note: Page number followed by *f* and *t* indicates figures and tables, respectively.

A

Abacavir (ABC), 60*t*, 1669
for HIV, 1637*t*
Abatacept, 914, 926*t*, 927, 931, 932
Abciximab, 254
Abilify (*see* Aripiprazole)
Abiraterone, 2151–2152, 2153
Abreva (*see* Docosanol cream)
Acamprosate, 1970–1971
Acarbose, for type 2 diabetes, 1158, 1169
ACE inhibitors (*see* Angiotensin-converting enzyme (ACE) inhibitors)
Acetaldehyde, 1963
Acetaminophen, 46, 51, 1220
analgesic syndrome from, 639
for arthritis, 2287
for burns, 898
for dysmenorrhea, 1047
for end-of-life care, 89
for HAV, 1724
hepatitis and, 1732
for migraine headache, 1266
neonates and, 2215, 2222
for OA, 898, 901
for PDA, 2239
PegIFN therapy, 1740
for postoperative pain management, 1220
pregnancy and, 81, 976*t*
toxicity with, 81–84
Acetazolamide, 595

cryptococcal disease, 1695
and hypokalemia, 615*t*
Acid-related disorders, pharmacotherapy of drugs
antacids, 505
antacids and alginic acid, 505
bismuth salts, 509
H_2-receptor antagonists, 507
misoprostol, 509
PPI, 507–509
sucralfate, 509
Acitretin, for psoriasis, 874*t*, 877–878
Aclidinium bromide, for COPD, 439*t*
Acular (*see* Ketorolac)
Acupressure, 1007
Acupuncture, 1007
ACV (*see* Acyclovir (ACV))
Acyclovir (ACV), 776, 1700*t*, 1701
administration of, 1701–1702
adverse effects of, 1381*t*, 1698, 1699*t*
dosing of, 1383*t*
for genital herpes, 1585, 1586*t*
for herpes encephalitis, 1698–1699
for herpes labialis, 1701–1702
for herpes simplex virus, 1203, 1699, 1701
kidney failure, dosing of drugs, 705
oral administration, 1699
pharmacokinetics of, 1706*t*
for PHN, 1703, 1708
toxicity, 1708
against varicella infection, 1703
Acyclovir and Hydrocortisone cream (Xerese), 1702
Acyclovir cream (Zovirax), 1702
ADACEL, 1408
Adalimumab, 914, 923, 926*t*, 932
for inflammatory bowel disease, 553*t*
for PsA, 879
for RA, 914
for UC, 560
Adapalene, 867, 868
Adefovir dipivoxil, 1740
Adenosine, 338–339
Ado-trastuzumab emtansine, 491*t*
Adrenaclick, 469*t*
Aerosolized aztreonam, 481
Afatinib, 492*t*

Aflibercept, 1205
Afrezza, 1115, 1117
Afrin (*see* Oxymetazoline)
Aggressive insulin therapy, 473
Akynzeo (*see* Palonosetron; Netupitant)
Alanine aminopeptidase, 2053
Albendazole, 1773*t*
for ascariasis, 1773*t*
for enterobiasis, 1773*t*
for filariasis, 1773*t*
for giardiasis, 1773*t*
for hookworm, 1774*t*
for hydatid cysts, 1775*t*
for pinworm, 1776
Albumin, 379
in edema, 594
Albuterol, 407, 721*t*
for acute asthma, 407
for AECOPD, 1462
anxiety from, 1806*t*
for chronic asthma, 413
for COPD, 438, 439*t*
for end-of-life care, 89
for hyperkalemia, 620*t*
with ipratropium, 90
nebulization, 407, 619
respiratory acidosis and, 597
Alcaftadine (Lastacaft), 460*t*, 1201
Alcohol, 1679
and acute gout, 946
AF and, 331*t*
for BMD, 2335
diabetes and, 1112
GERD and, 526*t*
heartburn and, 1009
HF and, 290
hypertension and, 146
MI and, 220*t*
for osteoporosis, 2346
pulmonary embolism and, 203
for schizophrenia, 1853*t*
teratogenic effects, 1004*t*
variant angina and, 238
Aldesleukin, 491*t*
Aldosterone antagonists

for ACS, 246*t*
for HF, 281, 307
for hypertension, 147, 155*t*, 157*t*, 164
in left ventricular remodeling, 267
Alectinib, 492*t*
Alemtuzumab (Campath), 492*t*, 1265
monoclonal antibodies, 756
for MS, 1255
Alendronate, 2342–2343, 2343*t*
androgen deprivation therapy, 2155
dose, 2342
for end-of-life care, 90
Alfentanil, 2189*t*
Alfuzosin, 2320
Alirocumab, 134–136
Aliskiren, 133, 164*t*, 639
for hypertension, 147, 165
Allegra (*see* Fexofenadine)
Allopurinol, 60*t*, 947, 948*t*
for HF, 293
weight gain with, 2080
Allylamines, 1676
Almotriptan, 1273
Alocril (*see* Nedocromil)
Alogliptin, 1161
Alomide (*see* Lodoxamide)
Alosetron, 569
Aloxi (*see* Palonosetron)
α-adrenergic agonists, 526*t*
α-adrenergic blockers, 2302
α-blockers, 165
with β-blockers, 166
for hypertension, 147
Alphagan (*see* Brimonidine)
α_2-adrenergic agonist, 1949
α_2-agonists
for ADHD, 1941–1942
for developmental disorders, 1927
for hypertension, 166
Alprazolam (Xanax), 1310*t*, 1311, 1807*t*, 1828
for panic disorder, 1815
sedative-hypnotics, 1952
Alprostadil, 2330
Alrex (*see* Loteprednol)
Alteplase, for STEMI patients, 254

Altretamine, 492*t*
Aluminum hydroxide, 651*t*
Aluminum salts, 509
Amantadine (Symmetrel), 1247, 1286*t*, 1297
adverse effects, 1699*t*
for Akathisia, 1870*t*
for influenza, 1708–1709
for Parkinsonism, 1870
AmB (*see* Amphotericin B (AmB))
AmB formulation, 1695
Ambien, 1835*t*
Ambien CR, 1835*t*
Ambrisentan, 133, 954
Ameliorate, 1949
Amifostine, 491*t*, 2039
Amikacin (Amikin), 482*t*, 1372*t*
adverse effects of, 1379*t*
for CAPD-associated peritonitis, 1533*t*
for CNS infections, 1426*t*
for gram-negative aerobes, 1374*t*
for MAC, 1671
pharmacodynamic actions of, 49
for tuberculosis, 1484*t*
for UTI, 1553*t*
Amikin (*see* Amikacin)
Amiloride, 576, 618
for hypertension, 156
Aminobenzoates, 887–888
Aminoglycosides, 475, 481, 1788
adverse effects of, 1379*t*
for CNS infections, 1426*t*
extended-interval dosing of, 482
kidney failure, dosing of drugs, 700–701
for NEC, 2243
for neutropenic patients, 1619, 1620
for pneumonia, 1473–1474
for RMSF, 1794
for sepsis, 2243
for UTI, 1553*t*
Aminopenicillin, 442
Aminophylline, 2246
Aminosalicylates, 556*t*
Aminosyn, 837*t*
Aminosyn HBC, 837*t*
Aminosyn II, 837*t*

Aminosyn-RF, 837*t*
Amiodarone, 125*t*, 225
for ACS, 246*t*
adverse effects of, 343
for AF, 334–335
antiadrenergic effects of, 344
for cardiopulmonary arrest, 349–350
for HF, 316–317
and liver toxicity, 344
and MI, 342
for SuVT, 342–343
for tachycardia, 1873
for ventricular arrhythmias treatment, 258
Amitriptyline, 569, 1227, 1229*t*, 1276, 1280
for depressive disorders, 1891*t*, 1892*t*
Amlodipine, 125*t*, 162, 225
for chronic stable angina pectoris, 225
for vascular dementia, 2302
Amoxicillin (Amoxil), 514*t*, 519, 948*t*, 976*t*, 1372*t*, 1788, 2222
Amoxicillin/clavulanate
for CAPD-associated peritonitis, 1533*t*
for COPD, 436
and potassium clavulanate, 1544*t*
PPI and, 518–519
for skin and soft tissue infections, 1606
for UTI, 1544*t*
Amoxil (*see* Amoxicillin)
Amphetamine, 1939, 1955
for ADHD, 1940*t*
CNS stimulants, 1995
and lactation, 1035*t*
for schizophrenia, 1853, 1853*t*
Amphotericin
for CAPD-associated peritonitis, 1533*t*
and hypokalemia, 615*t*
nephrotoxicity by, 1454
Amphotericin B (AmB), 1676, 1676*t*, 2069
5-FC and, 1454
adverse effects of, 1384*t*, 1684–1687
for aspergillosis, 1692–1693
candida infections
AmB-associated renal dysfunction, 1683
dose and duration of therapy, 1681*t*, 1683, 1684
infusion-related reactions, 1684–1685
for cryptococcal meningitis, 1665

every-other-day regimens, 1684
formulations, 1686*t*
for histoplasmosis, 1687
intrathecal administration of, 1692
for leishmaniasis, 1774*t*
risk factor B, 1687
for sepsis, 2244*t*
Amphotericin B deoxycholate (AmBD), 1625
Ampicillin (Omnipen), 948*t*, 976*t*, 1372*t*, 2189*t*
for aerobic gram-positive cocci, 1373*t*
allergy, 716
for anaerobes, 1374*t*
for CAPD-associated peritonitis, 1533*t*
for chorioamnionitis, 1029
for CNS infections, 1426*t*
dosing of, 1383*t*
for enterococcal endocarditis, 1451*t*
for gram-negative aerobes, 1374*t*
for NEC, 2243
for sepsis, 2244, 2244*t*
for UTI, 1544*t*, 1552*t*
Ampicillin-sulbactam
for CAPD-associated peritonitis, 1533*t*
for chorioamnionitis, 1029
dosing of, 1383*t*
for UTI, 1552*t*
Amprenavir, 133, 976*t*
Amylase, and respiratory alkalosis, 1732
Amylin receptor agonists
adverse effects of, 1162
contraindications and precautions of, 1162–1163
dosage and clinical use, 1163
drug interactions, 1163
efficacy of, 1163
mechanism of action, 1162
pharmacokinetics of, 1162
Anabolic steroids, for acne, 867
Anakinra, 915–916, 926*t*, 932
Analgesia, 1218*t*
Analgesics
for acute gout, 946
for burn pain, 898
for tension-type headache, 1280
Anastrozole, 1053
Ancef (*see* Cefazolin)

Androgen deprivation therapy (ADT), 2147*t*, 2146–2148
Androgen receptor antagonists for acne, 869
Androgens
for acne, 867
teratogenic effects, 1004*t*
Anesthesia, 2165
Angiotensin-converting enzyme (ACE) inhibitors, 266, 727–728, 948*t*, 1239
for ACS, 246*t*
agents of choice, 295–298, 296*f*
angioedema and, 301–302, 727
angiotensin receptor blockers and, 285, 298–300
CAD and, 154
CKD and, 154
cough and, 728
diabetes and, 153–154
in HFrEF, 297*t*
and hydralazine–isosorbide, 312–313
hyperkalemia and, 300–301
for hypertension, 146–147, 157*t*, 160–161
induced cough, 300
kidney function and, 302
left ventricular dysfunction and, 154
for PAD, 174
for patients with CKD, 648
for pregestational diabetes, 1010
pregnancy and, 161
side effects of, 302
teratogenic effects, 1004*t*
Angiotensin receptor blockers (ARBs), 222, 245, 727–728, 1016, 1240
for ACS, 246*t*
and angioedema, 301–302, 728
CAD and, 154
chronic kidney disease and, 154
diabetes and, 153–154
in HF, 298–300, 298*t*
for hyperkalemia, 300–301
for hypertension, 147, 157*t*, 161, 161*t*
and kidney function, 302
left ventricular dysfunction and, 154
side effects of, 302
Angiotensin receptor-neprilysin inhibitor (ARNI), 286
Anidulafungin, 1676, 1676*t*
adverse effects of, 1381*t*
Antacids, 505, 507, 747, 2039, 2040
for dyspepsia, 510

and fluoroquinolones, 42
for GER, 2218, 2220*t*
in preventing SRMB, 537, 537*t*
Anthracycline, 491*t*
Anthralin, for psoriasis, 873*t*, 875
Anthranilates, 885*t*, 888
Antiandrogen (*see* Spironolactone)
Antibiotics, 481
for acne, 867
for acute bronchitis, 1459
adverse effects of, 1379–1382*t*
for AECOPD, 1461–1462
for biliary infections, 1528
in brain abscess, 1434
for *Campylobacter* infection, 1512
for CAP, 1463–1464
for CAPD-associated peritonitis, 1533*t*
for *Chlamydia trachomatis*, 956
for chorioamnionitis, 1029
for chronic *S. typhi* carriers, 1510
for CNS infections, 1426*t*
combination therapy, 1388
with corticosteroids, 860
costs of, 1379
CSF penetration characteristics of, 1424*t*
diarrhea from, 1518
dosing of, 481–483, 1379–1382, 1383–1386*t*
drug selection, 481
failure with, 1389
for GBS infection, 1028
for hospital-acquired pneumonia, 1470–1474
host factors and, 1389
for Lyme disease, 1788
for nontyphoidal salmonellosis, 1508
for nosocomial UTI, 1553*t*
oral, 868
pharmacokinetics/pharmacodynamics of, 1387–1388
pharmacologic factors, 1389
for PPROM, 1027
and protein binding, 1388
for pyelonephritis, 1551
for relapsed UTI, 1554
resistance rates, 519
route of administration, 1379
in SBP treatment, 1530

for shigellosis, 1511
STEC treatment and, 1518
for surgery, 1391–1400
for travelers' diarrhea, 1514–1515
for typhoid fever, 1510
for UTI, 1536–1537
for *V. cholerae* infections, 1506
for *V. parahaemolyticus* gastroenteritis, 1506
topical, 868
Anticholinergics, 1296*t*
for asthma, 41
for COPD, 438, 440
for end-of-life care, 91
GERD and, 526*t*
for Parkinson disease, 1292
for schizophrenia, 1853
Anticonvulsants
for brain abscess, 1436–1437
for neuropathic pain, 1211
for PTSD, 1823
Antidepressants, 1848
for bipolar depression, 1918
and sleep, 1841
toxicity from, 79
tricyclic (*see* Tricyclic antidepressants)
Antidiarrheals, 569
Antiemetics, 1007, 1008*t*, 1273
for CINV, 473–496, 494*t*
Antiepileptics
for critically ill patients, 1240
for depressive disorders, 1887*t*
for seizures, 1316*t*
Antiestrogen (Clomiphene citrate), 991, 1046
for polycystic ovary syndrome, 1045*t*
Antifungals
adverse effects of, 1381*t*
antifungal spectrum and susceptibility testing, 1676
for blastomycosis during pregnancy, 1687
cryptococcal disease, 1695
mechanism of action, 1676–1677
novel antifungal compounds, 1676–1677
pharmacokinetic properties of systemically active, 1681*t*
prophylaxis regimens and approximate costs, 1678*t*
Antihistamines, 461*t*, 743, 1007, 1008*t*
for allergic rhinitis, 451, 455*t*

for anaphylaxis, 719, 721*t*
for rhinitis, 456–457
and sleep, 1833, 1845
Antimalarials, 739
Antimicrobials, 1374–1375*t*
costs of therapy, 1379
dosing, 1382–1387
toxicities, 1378–1379
Antimotility drugs, 1515–1516
Antimycotic pulse therapy, 1679
Antineoplastics, and lactation, 1035*t*
Antioxidants, 1303
as photoprotective agents, 889
Antipseudomonal penicillins, 706
Antipseudomonal β-lactam, 481
Antipsychotics
for acute agitation, 1916
for acute mania, 1915
for bipolar depression, 1907, 1917–1918
for critically ill patients, 1240
and lithium, 1914*t*
Antipyretics, 1724
Antiretroviral therapy (ART), 1029
Antispasmodics, 1225
for IBS, 568
Antispasticity agents, 1225
Antithymocyte globulin (ATG), 756–757
Antithyroid drugs, teratogenic effects, 1004*t*
Antivirals
adverse effects of, 1381*t*
in febrile neutropenic patient, 1626
for HBV, 1738
in immunocompromised patients, 1708
Anzemet (*see* Dolasetron)
Apidra (*see* Insulin glulisine)
Apixaban, 1359*t*
for prevention of stroke, 336–337
for stroke prevention, 184
for warfarin therapy, 205
Apokyn (*see* Apomorphine)
Apomorphine (Apokyn), 1287*t*, 1290*t*, 1297
Apraclonidine (Iopidine), 1186
Apremilast, for plaque psoriasis, 878
Aprepitant (Emend), 132, 494*t*, 976*t*
for CINV, 493–496, 494*t*, 497*t*, 498

drug interaction, 1812
duration of treatment, 1811–1812
and falls, 1811
and GABA-A receptors, 1809
for GAD, 1804
GERD and, 526*t*
induced sedation, management of, 1813
and lactation, 1846
LSD, 1957
for LTCF, 2289
mechanism of action, 1804
for panic disorder, 1917
physiological factors influencing, 1813

and pregnancy, 1846
and respiratory depression, 1811
for SAD, 1820
for schizophrenia, 1855
sedative-hypnotics, 1952
and sleep, 1832, 1833, 1846
with smoking, 1979*t*
tolerance of, 1841–1842
use during lactation, 1813
use in pregnancy, 1813
withdrawal syndrome, management of, 1812
Benzoic acid, 1678
Benzophenones, 885*t*, 888
Benzoyl peroxide, for maculopapular acne, 868–869
Benzphetamine, 799
Benztropine (Cogentin), 1286*t*
for Akathisia, 1870*t*
for Parkinsonism, 1870
Bepotastine (Bepreve), 460*t*
Bepreve (*see* Bepotastine)
β-adrenergic agonists, 1025
β-adrenergic blockers
for Akathisia, 1870
for patients with CKD, 648
for vascular dementia, 2302
β-adrenergic blocking agents, 332
β-adrenergic receptor blockers, 1093, 1820
β-blockers, 576, 583, 976*t*
for ACS, 246*t*, 257, 267
adrenergic blocking agents, 286
alcohol withdrawal, 1966
benefits of, 267
CAD and, 224
carvedilol *vs*. metoprolol, 304
in HFrEF, 302–304
in HTN, 313
for hypertension, 147, 157*t*, 166*t*
metoprolol vs. carvedilol, 304
for MI, 267
in severe heart failure, 304–305
teratogenic effects, 1004*t*
for thyroid storm, 1098
β-hydroxy-β-methylglutaryl-CoA (HMG-CoA), 257
β-lactam, 475, 481, 730, 1620
adverse effects of, 1379*t*

and aminoglycoside, 1619
antibiotics, 481
double combinations, 1619
for febrile neutropenia, 1619
Betamethasone, 1026
β_2-adrenergic agonists, 526*t*
β_2-agonists, 619
for AECOPD, 1462
for hyperkalemia, 620*t*
and hypokalemia, 615*t*
Betaxolol (Betoptic), 1187
adverse effects of, 1190
alternative therapy, 1190
initial therapy, 1190
patient education, 1190
Bethanechol, 2039, 2220*t*
Betoptic (*see* Betaxolol)
Bevacizumab (Avastin), 492*t*, 2038, 2054, 2118
for colon cancer, 2127, 2132
and hypertension, 2054
for metastatic colorectal cancer, 1205
Bexarotene, 492*t*, 976*t*
Biaxin (*see* Clarithromycin)
Bicalutamide, 2147
Bicarbonate (sodium bicarbonate), 672, 1009
-carbonic acid system, 643
adverse effects of, 382
hyperkalemia and, 619, 620*t*
for preventing SRMB, 537*t*
for salicylate toxicity, 72
for TCA toxicity, 80
BiDil (*see* Isosorbide dinitrate (BiDil))
Biguanide (Metformin)
adverse effects of, 1153
contraindications and precautions of, 1153
dosage and clinical use of, 1153
drug interactions, 1153
efficacy of, 1153
mechanism of action, 1153
pharmacokinetics of, 1153
for polycystic ovary syndrome, 1045*t*
for type 2 diabetes, 1174
Bile acid resins
adverse effects, 132
clinical pearls, 132

drug interactions, 132
efficacy, 131
mechanism of action, 131, 131*f*
pharmacokinetics/pharmacodynamics, 131
place in therapy, 132
Bilirubin, 31, 31*f*
blood chemistry reference values for, 20*t*
Bimatoprost (Lumigan), 1186
for ocular hypertension, 1186
Biperiden
for Akathisia, 1870*t*
for Parkinsonism, 1870
Biphosphonates, for hypercalcemia, 623*t*, 624
Bisacodyl, 2217*t*
for end-of-life care, 91
Bismuth salt, 509, 518–519
Bismuth subsalicylate (BSS)
for Helicobacter pylori, 514*t*
for infectious diarrhea, 1504
Bisoprolol
in HFrEF, 303
in hypertension, 166*t*
Bisphosphonates, 2349, 2352
and dyspepsia, 509
Bivalirudin, 264
for ACS, 247*t*
for heparin-induced thrombocytopenia, 185
Blenoxane (*see* Bleomycin)
Bleomycin (Blenoxane), 492*t*, 2042, 2043*t*, 2050, 2054*t*, 2055, 2056
gonadal toxicity of, 2058
Boceprevir, 125*t*, 132
for HAV, 1750
Bonine (*see* Meclizine)
BOOSTRIX, 1408
Borates, 1678
Boric acid, for VVC, 1581
Bortezomib (Velcade), 492*t*, 2094
neurotoxicity of, 2048*t*
peripheral nerve toxicity of, 2048
Bosentan, 954, 976*t*
for pulmonary HTN, 279
Bosutinib, 492*t*
Botulinum toxin A, 1310*t*, 1311
Brentuximab vedotin, 491*t*
Brevibloc (*see* Esmolol)

Brexpiprazole (Rexulti), 1857, 1860*t*
for Akathisia, 1870
Brimonidine (Alphagan), 1186
Brinzolamide (Azopt), 1188
Brisdelle (*see* Paroxetine mesylate)
Brivaracetam, 1322*t*
Bromocriptine (Parlodel), 1286*t*, 1290*t*, 2330
and lactation, 1033
for type 2 diabetes, 1165
Bronchodilators, for COPD, 434–435, 442
BSS (*see* Bismuth subsalicylate (BSS))
Budesonide, 461*t*
for allergic rhinitis, 462
for BPD, 2233
for chronic asthma, 413, 415
for COPD, 439*t*
for inflammatory bowel disease, 550*t*
Budesonide/formoterol (Symbicort), 415
Bumetanide, 676
for HF, 292
Bupivacaine hydrochloride, 1215*t*
Bupivacaine liposomal, 1215*t*
Buprenorphine, for opioid withdrawal syndrome, 1949
Bupropion, 1898
for ADHD, 1943
for depressive disorders, 1891*t*, 1892*t*
Bupropion/zonisamide ER, 801
for bipolar depression, 1907
and sleep, 1843
for smoking cessation, 1987
sustained-release, 1981, 1988–1989, 1993
BuSpar (*see* Buspirone)
Buspirone (BuSpar), 1808*t*, 1809, 1814
vs. benzodiazepines, 1814
and elderly, 1809
Busulfan (Busulfex, Myleran), 491*t*, 492*t*, 2056*t*
Butenafine, 1676*t*
Butoconazole, 1676*t*
for VVC, 1580*t*
Butyrophenone, 1858*t*

C

Cabazitaxel (Jevtana), 491*t*
peripheral nerve toxicity of, 2048

for prostate cancer, 2151
Cabozantinib, 492*t*
Caffeine, 803*t*, 976*t*
for apnea, 2246
for BPD, 2246
drug interaction with smoking, 1978*t*
and heartburn, 1009
and lithium, 1914*t*
and pregnancy, 1002
Calamine lotion, 862
Calcimimetics, 653
Calcineurin inhibitors, 658, 755
for FSGS patients, 658–659
induced nephrotoxicity, 763
Calcitonin, 2343*t*, 2349
for hypercalcemia, 623*t*, 624
for osteoporosis, 2348
Calcitriol, 652
for psoriasis, 875
Calcium, 26–27
blood chemistry reference values for, 19*t*
and BP, 141
and children, 2198*t*
for endometriosis, 1053
homeostasis, 620–621
hypercalcemia, 622–625
for PMS, 1054
and pregnancy, 1000
recommended daily allowance, 1000
and respiratory alkalosis, 1731
role of, 620
Calcium acetate, 651*t*
Calcium carbonate, 651*t*
Calcium-channel blockers (CCBs), 176, 220
for ACS, 247*t*
for AF, 332–333
in anginal syndromes, 225
CAD and, 154
diabetes and, 162–163
dihydropyridines, 162
GERD and, 526*t*
hemodynamic and electrophysiologic profile, 232*t*
for HF, 287
for hypertension, 147, 162–163, 163*t*
for hyperthyroidism, 1081, 1091*t*

nondihydropyridines, 162
in patients with CKD, 648
for pregestational diabetes, 1010
for PSVT, 339
vasospastic and classic exertional angina, 232
Calcium gluconate, 620*t*
Campath (*see* Alemtuzumab)
Camphor, 1678
Canagliflozin, 1163
Canakinumab, 932, 946
Canasa, 556*t*
Candesartan, 1277
for HF, 285, 299
for hypertension, 161*t*
Candicidin, 1678
Cangrelor, 255–256*t*
for ACS, 247*t*
for thrombotic events reduction, 254
Cannabidiol, 1322*t*
Cannabinoids, 1257
for CINV, 496
Cannabis, 1853, 1853*t*
Capecitabine (Xeloda), 492*t*, 2054*t*
Capoten (*see* Captopril)
Capreomycin, for tuberculosis, 1485*t*
Caprylic acid, 1678
Capsaicin
for neuropathic pain, 1211
for OA, 903
Capsaicin cream
for PHN, 1705
Capsaicin patch, 1705
Captopril (Capoten), 179, 266, 296–297, 296*t*, 354*t*
for BP, 354
and hyperkalemia, 617
in hypertension, 160*t*
Carbachol (Isopto Carbachol), 1198
Carbamazepine (CBZ), 43, 60, 225, 976*t*, 1317*t*, 1325*t*, 1812, 1823, 1907, 2325*t*
for acute mania, 1915
autoinduction of metabolism of, 1320
bioequivalence of generic dosage of, 1320–1321
for bipolar disorder, 1919*t*
for epilepsy, 59
extended-release forms of, 1321
for HAV, 1751

and hematologic toxicity, 1319–1320
hepatotoxicity with, 1319–1320
initiation and dosage of, 1319
lamotrigine and, 1328
and lithium, 1914*t*
for ocular emergencies, 1196*t*
pharmacokinetics of, 1320
for schizophrenia, 1875
for seizures, 1319
teratogenic effects, 1004*t*
valproate and, 1337
Carbamazepine, 1228*t*, 1322*t*
Carbapenem
for febrile neutropenia, 1618
for skin and soft tissue infections, 1608
for UTI, 1553*t*
Carbidopa–levodopa (enteral suspension) (Duopa), for Parkinson disease, 1286*t*
Carbidopa–levodopa (CR) (Sinemet CR), for Parkinson disease, 1286*t*
Carbidopa–levodopa (ER) (Rytary), for Parkinson disease, 1286*t*, 1297
Carbidopa–levodopa ODT (Parcopa), for Parkinson disease, 1286*t*
Carbonyl iron, 1999
Carboplatin (Paraplatin), 491*t*, 2054*t*, 2118
for NSCLC, 2114*t*, 2115*t*
for SCLC, 2120*t*
Carboprost tromethamine, for postpartum hemorrhage, 1030–1031, 1030*t*
Cardene IV (*see* Nicardipine)
Cardiac resynchronization therapy (CRT), 28
Carfilzomib, 491*t*
Cariprazine (Vraylar)
for acute mania, 1916*t*
for schizophrenia, 1858, 1860*t*
Cariprazine, 1868*t*, 1916
for bipolar depression, 1918*t*
Carisoprodol, 1126*t*
Carmustine (BiCNU), 205*t*, 491*t*, 2054*t*, 2056, 2056*t*
and cranial neuropathies, 2049
Carteolol (Ocupress), 1187
Carvedilol, 267
in HFrEF, 303–304
for hypertension, 166, 166*t*
in peri-infarction period, 262, 267
Caspofungin, 1626, 1676*t*, 1677, 1685, 1692
adverse effects of, 1381*t*
dosing of, 1383*t*

for fungal endocarditis, 1454
Catapres (*see* Clonidine)
Catechol-O-methyltransferase inhibitors (COMT), 1299–1301
pharmacologic and pharmacokinetic properties of, 1300*t*
Catecholamines, for septic shock, 392
Cathelicidins, 1677
CBZ (*see* Carbamazepine (CBZ))
CCBs (*see* Calcium-channel blockers (CCBs))
Ceclor (*see* Cefaclor)
Cedax (*see* Ceftibuten)
Cefaclor (Ceclor), 1372*t*
for chronic antimicrobial therapy, 1556*t*
for UTI, 1544*t*
Cefadroxil (Duricef), 1372*t*
Cefamandole (Mandol), 1372*t*
Cefazolin (Ancef), 1201, 1372*t*, 1604
for aerobic gram-positive cocci, 1373*t*
for anaerobes, 1374*t*
for CAPD-associated peritonitis, 1533*t*
dosing of, 1383*t*
for gram-negative aerobes, 1374*t*
kidney failure, dosing of drugs, 707–708
for PVE, 1446*t*
for pyelonephritis, 1028
for skin and soft tissue infections, 1604
for surgical procedures, 1392*t*, 1396
for UTI, 1552*t*
Cefdinir (Omnicef), 1372*t*
Cefditoren (Spectracef), 1372*t*
Cefepime (Maxipime), 1372*t*
for aerobic gram-positive cocci, 1373*t*
for anaerobes, 1374*t*
for CAPD-associated peritonitis, 1533*t*
for CNS infections, 1426*t*
for cystic fibrosis, 482*t*
dosing of, 1383*t*
for febrile neutropenia, 1618
for gram-negative aerobes, 1374*t*
for gram-negative bacillary meningitis, 1432
for skin and soft tissue infections, 1606
for UTI, 1552*t*
Cefixime (Suprax), 1372*t*
for disseminated gonococcal infection, 1570
for shigellosis, 1511
for typhoid fever, 1511

for uncomplicated gonorrhea, 1564
Cefizox (*see* Ceftizoxime)
Cefonicid (Monocid), 1372*t*
Ceforanide (Precef), 1372*t*
Cefotaxime (Claforan), 1372*t*
for anaerobes, 1374*t*
and biliary pseudolithiasis, 1428
for CNS infections, 1426*t*
for NEC, 2243
for sepsis, 2244*t*
for UTI, 1497*t*, 1552*t*
Cefotetan (Cefotan), 1372*t*
for anaerobes, 1374*t*
for chorioamnionitis, 1029
for PID, 1569*t*
Cefoxitin (Mefoxin), 1372*t*
for chorioamnionitis, 1029
for PID, 1569*t*
Cefpodoxime proxetil (Vantin), 1372*t*
for UTI, 1544*t*
Cefprozil (Cefzil), 1372*t*
Ceftaroline (Teflaro), 1372*t*, 1424, 1447
for aerobic gram-positive cocci, 1373*t*
for gram-negative aerobes, 1374*t*
for skin and soft tissue infections, 1604
for UTI, 1552*t*
Ceftazidime (Fortaz), 483, 704, 1372*t*
for anaerobes, 1375*t*
for CAPD-associated peritonitis, 1533*t*
for cystic fibrosis, 482*t*
dosing of, 1383*t*
for febrile neutropenia, 1619
for gram-negative aerobes, 1374*t*
for gram-negative bacillary meningitis, 1432
kidney failure, dosing of drugs, 700–701
for skin and soft tissue infections, 1606
for UTI, 1552*t*
Ceftazidime-avibactam, 1374*t*
Ceftibuten (Cedax), 1372*t*
Ceftin (Cefuroxime axetil), 1372*t*
Ceftizoxime (Cefizox), 1372*t*
for anaerobes, 1375*t*
for CAPD-associated peritonitis, 1533*t*
Ceftolozane/tazobactam (Zerbaxa), 1372*t*, 1424, 1455
for gram-negative aerobes, 1374*t*

Ceftriaxone (Rocephin), 582, 723, 1372*t*, 1424, 1429, 1455, 1789, 1792, 2189*t*
and aminoglycoside, 1443
for anorectal gonorrhea, 1566
and biliary pseudolithiasis, 1428
for CNS infections, 1426*t*
for disseminated gonococcal infection, 1570
dosing of, 1383*t*
for endocarditis, 1443
for neonatal DGI, 1570
for skin and soft tissue infections, 1604
for tularemia, 1792
for typhoid fever, 1508
for uncomplicated gonorrhea, 1564*t*, 1565
for UTI, 1552*t*
Cefuroxime (Zinacef), 1372*t*, 2189*t*
for aerobic gram-positive cocci, 1373*t*
for gram-negative aerobes, 1374*t*
for N. meningitides, 1426
for UTI, 1552*t*
Cefuroxime axetil (Ceftin), 1372*t*, 1789
Cefzil (*see* Cefprozil)
Celecoxib, 57, 513, 739, 904, 905*t*, 918
Celexa (*see* Citalopram)
Cenobamate, 1322*t*
Central α_2-agonists, for hypertension, 148
Cephalexin (Keflex), 1009, 1372*t*
for chronic antimicrobial therapy, 1556*t*
for pyelonephritis, 1009
for skin and soft tissue infections, 1603
for UTI, 1544*t*
Cephalosporins, 717, 1425, 1788, 1794
adverse effects of, 1379*t*
for cardiac surgery prophylaxis, 1445–1446
for chorioamnionitis, 1029
for CNS infections, 1426*t*
during pregnancy, 1009
for tularemia, 1794
for uncomplicated gonorrhea, 1564*t*, 1565
for UTI, 1552*t*
Ceritinib, 492*t*
Certolizumab
for CD, 562
for inflammatory bowel disease, 554*t*
pegol, 914, 915, 923, 926*t*
Cerubidine (*see* Daunorubicin)

Cesamet (*see* Nabilone)
Cetilistat, 802
Cetirizine (Zyrtec), 455*t*
for rhinitis, 458
and sleep, 1836
Cetuximab (Erbitux), 492*t*
for colon cancer, 2127
Cevimeline, 2039
CFTR potentiator, 479–480
Chasteberry (Vitex agnus-castus or VAC), 1056
ChEIs (*see* Cholinesterase inhibitors (ChEIs))
Chemoprophylaxis, for OIs, 1656
Chemotherapy
for acute leukemia, 2057
for acute myeloid leukemia, 2057
for acute tubular obstruction, 2054
for aggressive lymphomas, 2093
in ALL, 2075
and alopecia, 2041
for AML, 2085
and anemia, 2037
for arrhythmias, 2052
for autonomic neuropathy, 2049
for B-cell lymphoma, 2079–2080
on bone marrow, 2035–2038
for cardiomyopathy, 2049–2050
and cardiotoxicity, 2049–2050
and colony-stimulating factors, 2035–2036
and cranial nerve toxicity, 2049
cytotoxic effects, 2035
dermatologic impacts, 2038–2041
and diarrhea, 2041
dosage regimen for intrathecal, 2075*t*
dosing in infants and young children, 2067
and dry skin, 2037
and esophagitis, 2040
and esophagus, 2040
and filgrastim, 2036, 2037
and GI tract, 2038–2041
and hand-foot syndrome, 2042
hematologic effects, 2035–2038
and hemorrhagic cystitis, 2054–2055
for HL, 2091
hypersensitivity reactions, 2044–2045
and hypertension, 2053

for indolent NHLs, 2095
induction combination, 2073–2074
interaction with radiation therapy, 2042–2043, 2043*t*
intrathecal prophylaxis, 2075
irritant and vesicant reactions, 2043
for large cell lymphomas, 2080
and life-threatening neutropenia, 2035
long-term complications, 2057–2058
for lymphoblastic (T-cell) lymphoma, 2077–2078
and mucositis, 2039–2040
and myelosuppression, 2035–2036
and myocardial infarction, 2052
nausea and vomiting, 2038
nephrotoxicity, 2052–2054, 2054*t*
for neuroblastoma, 2063
neurotoxicity, 2047–2049, 2048*t*
and neutropenia, 2035–2036
for NSCLC, 2115
and oral cavity complications, 2038–2039
for osteosarcoma, 2068
ototoxicity, 2049
for pediatric ALL, 2073
and pegfilgrastim, 2036
peripheral nerve toxicity, 2048
and peripheral neuropathy, 2048–2049
and pigment changes, 2042
and proteinuria, 2054–2055
and pulmonary functions, 2055–2056
for rhabdomyosarcoma, 2070–2071
skin and nail changes, 2042
for specific organs, 2047–2049
and stomatitis, 2039–2040
and thrombocytopenia, 2035, 2037
venous thrombotic events, 2038
and Wilms tumor, 2065–2067
and xerostomia, 2039
Chitosan, 803*t*
Chlor-Trimeton (*see* Chlorpheniramine)
Chlorambucil (Leukeran), 492*t*
for CLL, 2095
Chloramphenicol (Chloromycetin), 1372*t*, 1788
adverse effects of, 1380*t*
for RMSF, 1794
for tularemia, 1794
Chlordiazepoxide, 1807*t*

Chlorhexidine gluconate, 2040
Chloride, 23
blood chemistry reference values for, 18*t*
Chloromycetin (*see* Chloramphenicol)
Chloroprocaine, 1215*t*
Chloroquine, 51, 739, 765*t*, 1763
psoriasis and, 872
Chlorpheniramine (Chlor-Trimeton), 455*t*
Chlorpromazine, 1306, 1858*t*, 1868*t*, 1869*t*
for hyperprolactinemia, 1874
for schizophrenia, 1864*t*
Chlorpropamide, 1174
Chlorthalidone, 156
Chlorzoxazone, 1126*t*
Cholecalciferol, 2343*t*
Cholestyramine, 132, 741
for IBS-D, 569
for thyroid storm, 1098
Cholinesterase inhibitors (ChEIs), 1305
for Alzheimer disease, 2298
for DLB, 2300
for PDD, 2300
for vascular dementia, 2303
Chondroitin, 901
Chorioamnionitis, 1024
Ciclesonide (Omnaris, Zetonna), 461*t*
for allergic rhinitis, 462
Ciclopirox, 1676*t*
Cidofovir (Vistide), 777–778, 1666, 1700*t*, 1703
adverse effects, 1699*t*
for CMV retinitis, 1665
Cilostazol, 175, 1358*t*, 1359
for diabetes, 175
for IC, 175
Cimetidine, 506*t*, 507, 977, 2220*t*
inhibition of CYP450 isoenzymes, 507
for preventing SRMB, 537*t*
Cinacalcet, 653
Cinnamates, 885*t*, 888
Cinoxate, 885*t*
Cipro (*see* Ciprofloxacin)
Ciprofloxacin (Cipro), 483, 485, 976*t*, 1372*t*, 1429, 1447, 1793
for aerobic gram-positive cocci, 1373*t*
and AIN, 674
for anaerobes, 1375*t*

for CAPD-associated peritonitis, 1533*t*
for COPD, 442
for cystic fibrosis, 482*t*
dosing of, 1384*t*
for MAC, 1671
for S. dysenteriae type 1 infection, 1511
for travelers' diarrhea, 1516*t*
for tularemia, 1793
for UTI, 1544*t*, 1553*t*
Cisatracurium, 48
Cisplatin, 491*t*, 2038, 2043*t*
and cranial neuropathies, 2049
gonadal toxicity of, 2057–2058
and hypokalemia, 615*t*
monitoring hydration for, 2065
nephrotoxicity of, 2052–2054, 2065
for neuroblastoma, 2063, 2065
neurotoxicity of, 2048*t*, 2049
for NSCLC, 2114*t*, 2115, 2115*t*
for osteosarcoma, 2068
peripheral nerve toxicity of, 2048
and renal insufficiency, 2054*t*
for SCLC, 2120–2121, 2120*t*
weight gain with, 2065
Citalopram (Celexa), 346, 1305, 1808*t*, 1916
for agitated behaviors, 2305
for ASD, 1931
for depressive disorders, 1891*t*, 1892*t*, 2306
for OCD, 1822
for panic disorder, 1816
for PTSD, 1824
for vasomotor symptoms, 1039*t*
Citrus aurantium*, 803*t
Cladribine, 492*t*
Claforan (*see* Cefotaxime)
Clarinex (*see* Desloratadine)
Clarithromycin (Biaxin), 125*t*, 132, 514*t*, 519, 976*t*, 1372*t*, 1424, 1664, 1789
adverse effects of, 1380*t*
for aerobic gram-positive cocci, 1373*t*
for MAC, 1671
Claritin (*see* Loratadine)
Clavulanate, 482*t*
Clavulanic acid, 442
Clemastine (Tavist), 455*t*
Cleocin (*see* Clindamycin)

Clevidipine (Cleviprex), 353*t*
for hypertension, 363
Cleviprex (*see* Clevidipine)
Climara Pro, 1066*t*
Clindamycin (Cleocin), 1372*t*, 1664, 1764, 1796
for acne, 869
adverse effects of, 1380*t*
for aerobic gram-positive cocci, 1373*t*
for anaerobes, 1375*t*
for cellulitis, 674
for chorioamnionitis, 1029
dosing of, 1384*t*
for GBS infection, 1028
plus gentamicin, 1569*t*
for skin and soft tissue infections, 1603, 1604, 1605, 1606
Clindamycin-quinine, 1796
Clioquinol, 1676*t*
Clobazam, 1323*t*
Clofarabine (Clolar), 491*t*, 2056, 2056*t*
Clofazimine, 1671
Clofibric acid, 976*t*
Clolar (*see* Clofarabine)
Clomiphene citrate (Antiestrogen), 991, 1046
for polycystic ovary syndrome, 1045*t*
Clomipramine
for ASD, 1929
dosage, 1828
for panic disorder, 1817
side effects, 1829
Clonazepam, 1310*t*, 1311, 1807*t*
for Akathisia, 1870*t*
for panic disorder, 1816
for SAD, 1821
Clonidine (Catapres), 164*t*, 354*t*, 1846, 2325*t*
for ADHD, 1940*t*, 1941
alcohol withdrawal, 1966
for BP, 354
for hypertension, 167
for hypertensive urgency, 354
for opioid withdrawal syndrome, 1949
in patients with CKD, 648
for sleep, 1932
for vasomotor symptoms, 1069*t*
Clopidogrel, 208, 238, 508, 1154, 1358*t*, 1359
for ACS, 247*t*, 254, 255–256*t*

antiplatelet medications, 522
and aspirin, 247–248*t*, 1359
for CAD, 236
for diabetes, 175
drug interaction with smoking, 1978*t*
in fibrinolytic therapy, 260
for ischemia, 264
loading dose, 264–265
for MI, 223
for PAD, 175
for ulcer healing, 522

for warfarin therapy, 206
Dabrafenib, 492*t*
Dacarbazine (DTIC), 491*t*, 2043*t*, 2054*t*
Daclatasvir, for HAV, 1752
Dacogen (*see* Decitabine (Dacogen))
Dactinomycin (Cosmegen), 491*t*, 2043*t*
hepatotoxicity of, 2067
for rhabdomyosarcoma, 2070
Dalbavancin (Dalvance), 1447
adverse effects of, 1380*t*
for aerobic gram-positive cocci, 1373*t*
Dalfampridine, 1256
Dalfopristin/Quinupristin (Synercid), 1372*t*
adverse effects of, 1380*t*
Dalteparin, 183*t*, 195*t*, 196
Dalvance (*see* Dalbavancin)
Danazol, 125*t*
adverse effects, 1054
for endometriosis, 1052
Dantrolene, 1257
Dapagliflozin, 1163
Dapsone, 1661
DAPT therapy and outcomes, 270–271*t*
Daptacel, 1408
Daptomycin (Cubicin), 1372*t*, 1448
adverse effects of, 1380*t*
for aerobic gram-positive cocci, 1373*t*
for CAPD-associated peritonitis, 1533*t*
dosing of, 1384*t*
for endocarditis, 1450
enterococcal endocarditis and, 1453
MRSA, 1606
for skin and soft tissue infections, 1604
Darbepoetin alfa (Aranesp), 646
for anemia, 2011
Darifenacin, 2314
Darunavir (DRV), 133, 976*t*, 1639*t*
Dasabuvir, for HAV, 1752

Dasatinib (Sprycel), 492*t*, 2052, 2089
Daunorubicin (Cerubidine), 491*t*, 2042, 2043*t*, 2050
for AML, 2085
and hepatic dysfunction, 2056*t*
for T-cell lymphomas, 2079*t*
dDAVP (*see* desmopressin)
ddI (*see* Didanosine (ddI))
Decadron (*see* Dexamethasone)
Decitabine (Dacogen), 492*t*
Decongestant
for allergic rhinitis, 451, 455*t*
for rhinitis, 458–459
DEET (*see N,N*-diethyl-*m*-toluamide (DEET))
Deferasirox, for vaso-occlusive complications, 2010
Deferoxamine (DFO)
in iron toxicity, 75
for vaso-occlusive complications, 2010
Defibrillator, role of, 317
DEKAs Plus chewable tablet, 477*t*
DEKAs Plus liquid, 477*t*
DEKAs Plus softgel capsules, 477*t*
Delavirdine (DLV), for HIV, 1640*t*
Δ-9-tetrahydrocannabinol (THC), 1956
Delzicol (*see* Mesalamine)
Demeclocycline, 613
Demerol (*see* Meperidine)
Denavir (*see* Penciclovir cream)
Denileukin diftitox, 492*t*
Denosumab, 2343*t*, 2349–2350, 2352
androgen deprivation therapy, 2155
for prostate cancer, 2154
Deoxycholate, for sepsis, 2244*t*
Depacon, 1340
Depo-Provera, 980–981
Depot medroxyprogesterone acetate (DMPA), 1054
Desferal, in iron toxicity, 75
Desiccated thyroid, 1081
Desipramine (*see also* Antidepressants)
for depressive disorders, 1891*t*, 1892*t*
Desloratadine (Clarinex), 455*t*
for rhinitis, 458
Desmopressin (dDAVP), 676
Desogestrel, 968–970*t*, 977
Desvenlafaxine (Pristiq)
for depressive disorders, 1891*t*, 1892*t*

for serotonin, 1897
for vasomotor symptoms, 1069*t*
Dexamethasone (Decadron), 494*t*, 1027, 1691, 2087, 2094
for bacterial meningitis, 1425
for BPD, 2232
for PONV, 501*t*
for prostate cancer, 2152
for T-cell lymphomas, 2079*t*
Dexedrine (*see* Dextroamphetamine)
Dexlansoprazole, 506*t*, 1249*t*
Dexmedetomidine, 1245
for pediatric intubation, 2259*t*
Dexmethylphenidate, for ADHD, 1939*t*
Dexrazoxane, 492*t*, 2044, 2051
Dextran component, 644
Dextroamphetamine (Dexedrine), 490*t*, 1847
Dextromethorphan, 1258, 1267
dissociative drug, 1956
quinidine combination, for agitated behaviors, 2305
Dextrorphan, 1956
Dextrose, 834
DFO (*see* Deferoxamine (DFO))
DHA (*see* Dicosohexanoic acid (DHA))
DHAP, for aggressive lymphomas, 2091–2092
DHEAS (*see* Dehydroepiandrosterone sulfate (DHEAS))
DHT (*see* Dihydrotestosterone (DHT))
Diazepam, 599, 1020, 1807*t*, 1811, 1814, 2189*t*
for Akathisia, 1870*t*
febrile seizures and, 1336
PCP-induced seizures, 1956
for pediatric intubation, 2258*t*
in SE, 1341
for Tardive dyskinesia, 1872
Dibenzoxazepine, 1858*t*
Dibenzoylmethanes, 885*t*, 888
Diclegis, 1007
Diclofenac, 57, 905*t*, 906, 917
Diclofenac gel, 903
Diclofenac patch, 903
Diclofenac topical solution, 903
Dicloxacillin, 674, 1372*t*
for skin and soft tissue infections, 1603
Dicyclomine (*see* Antispasmodics)
Didanosine (ddI), 949*t*
for HIV, 1638*t*

for HIV in labor, 1029
for HIV-related anemia, 2012
Dienogest, 971*t*
Diethylcarbamazine, for amebic liver abscess, 1773*t*
Diethylpropion, 799
Diethylstilbestrol, teratogenic effects, 1004*t*
Dificid (*see* Fidaxomicin)
Diflucan (*see* Fluconazole)
Diflunisal, 905*t*
Digitalis (Digoxin), 133, 225, 505, 698, 2189*t*
for AF, 331–332
doses of, 309
drug interactions, 310*t*
effect on mortality, 308–309
efficacy of, 308
for HF, 281, 286
and hyperkalemia, 618
monitoring parameters, 309
serum drug concentrations, 309
sex differences in response to, 309
toxicity, 311
withdrawal trials, 308
Digitalis glycosides, for HF, 308–311
Digoxin (*see* Digitalis)
Dihydroergotamine, 1273, 1274
Dihydropyridine calcium-channel blockers, for vascular dementia, 2302
Dilaudid (*see* Hydromorphone)
Diloxanide furoate, 1773
for amebicides, 1773*t*
Diltiazem, 125*t*, 133, 162, 224, 640, 1093, 2325*t*
for AF, 333
for HF, 291
for HFpEF, 28, 287
in patients with CKD, 648
for thyroid storm, 109
Dimenhydrinate (Dramamine), 490*t*
for NVP, 1007, 1008*t*
Dimethyl fumarate, for MS, 1255, 1260
Dinoprostone cervical gel, 1022
Dinoprostone slow-release insert (Cervidil), 1022
Dinutuximab, 491*t*
Dioxybenzone, 885*t*, 888
Dipalmitoylphosphatidylcholine (DPPC), 2227
Dipentum (*see* Olsalazine)
Dipeptidyl peptidase-4 inhibitors (DPP-4)

adverse effects of, 1161
contraindications and precautions of, 1161
dosage and clinical use, 1162
drug interactions, 1161–1162
efficacy of, 1162
mechanism of action, 1161
pharmacokinetics of, 1161
Diphenhydramine (Benadryl), 455*t*, 1846
for Akathisia, 1870*t*
for NVP, 1007, 1008*t*
for Parkinsonism, 1870
for sleep, 1932
Diphenoxylate, 569
Diphenoxylate/atropine, 1503
Diphtheria, tetanus, and acellular pertussis (DTaP), 1405
vaccines, 1408
Dipyridamole, 1358*t*, 1359
Direct oral anticoagulants (DOACs), 187
advantages of, 194
dosing for AF and VTE, 186*t*
drug interactions with, 186*t*
for management of PE, 198
pharmacokinetic and pharmacodynamics properties of, 185*t*
for stroke prevention, 201
for VTE treatment, 201
Direct thrombin inhibitors
for heparin-induced thrombocytopenia, 185
injectable, 187*t*
Direct vasodilators, for hypertension, 148
Dirithromycin (Dynabac), 1372*t*
Diskus, for chronic asthma, 413, 415
Disopyramide
for HF, 291
for tachycardia, 1873
Disulfiram, alcohol withdrawal, 1968, 1970
Diuretics
adverse effects of, 293–294
and azotemia, 293
and BNP, 293
combination therapy of, 295
for dysmenorrhea, 1048
for HF, 284
for hypertension, 147, 155–158
and hyperuricemia, 293
and hypokalemia, 158, 293

hypomagnesemia and, 159, 293
and hyponatremia, 159, 293
loop, 619
and metabolic alkalosis/acidosis, 606
monitoring parameters with, 296*t*
for nephrotic edema, 607
osmotic, 628
for PMS, 1057
thiazide, 622, 2325*t*
Divalproex, 1275, 1332, 1919*t*
Divigel (*see* Estradiol gel; Estradiol topical emulsion/gel/solution)
DLV (*see* Delavirdine (DLV))
DMPA (*see* Depot medroxyprogesterone acetate (DMPA))
DOACs (*see* Direct oral anticoagulants (DOACs))
Dobutamine, 221, 2267*t*, 2269
in cardiac failure, 384–385, 384*t*
for cardiogenic shock, 384–385
for HF, 287, 315
for septic shock, 393–394
for tachycardia, 386
Docetaxel, 491*t*, 496, 2043*t*, 2052
and hepatic dysfunction, 2056*t*
for NSCLC, 2114*t*
peripheral nerve toxicity of, 2048
for prostate cancer, 2150
Docosahexaenoic acid (DHA), 130
Docosanol cream (Abreva), 1702
Dofetilide
for AF, 334
for SuVT, 344
for tachycardia, 1873
for WPW, 339
Dolasetron (Anzemet), 494*t*
for PONV, 501*t*
Donepezil
for Alzheimer disease, 2298–2299
for vascular dementia, 2303
Dopamine, 671, 721*t*, 1257, 2267*t*, 2269
for cardiac performance, 383–384, 384*t*
for cardiogenic shock, 383–384
GERD and, 526*t*
for HF, 287, 315
for hyperprolactinemia, 1874
for mild hypotension, 384–385
for NVP, 1008*t*

for septic shock, 393
for Tardive dyskinesia, 1872
Dopamine agonists, 1288–1289
adverse effects of, 1291
dosage of, 1292
for Parkinson disease, 1289–1292
Doral (*see* Quazepam)
Doribax (*see* Doripenem)
Doripenem (Doribax), 1372*t*
for skin and soft tissue infections, 1606
Dornase alfa, 478
Dorzolamide (Trusopt), 1198
Doxazosin, 164*t*, 2320, 2325*t*
for BPH, 2320
in patients with CKD, 648
Doxepin (Silenor)
for depressive disorders, 1891*t*
for pruritus, 861
for treatment of insomnia, 1835*t*
Doxercalciferol, 653
Doxorubicin, 491*t*, 2042, 2043, 2043*t*, 2049–2050, 2063, 2065, 2093
for breast cancer, 2103
and cardiomyopathy, 2049–2050
cardiotoxicity of, 2067
gonadal toxicity of, 2058
for osteosarcoma, 2068
for rhabdomyosarcoma, 2070
for T-cell lymphomas, 2079*t*
Doxycycline, 957, 976*t*, 1372*t*, 1766*t*, 1788, 1792
for acne, 868, 869
for cellulitis, 674
for COPD, 436
dosing of, 1384*t*
for HGA, 1794
for HME, 1794
for Lyme disease, 1788
for lymphogranuloma venereum, 1570
for malaria prophylaxis, 51
for PID, 1569*t*
for RMSF, 1794
for skin and soft tissue infections, 1603, 1608
for TBRF, 1792
for tularemia, 1793
Doxylamine, 1846
for NVP, 1007, 1008*t*

DPP-4 (*see* Dipeptidyl peptidase-4 inhibitors (DPP-4))
DPPC (*see* Dipalmitoylphosphatidylcholine (DPPC))
Dramamine (*see* Dimenhydrinate)
Dronabinol (Marinol), 494*t*
Dronedarone, 125*t*
for AF, 334
for HF, 291
Droperidol (Inapsine), 494*t*
for NVP, 1008–1009, 1008*t*
for PONV, 501*t*
Drospirenone, 1046, 1057
DRV (*see* Darunavir (DRV))
DTaP (*see* Diphtheria, tetanus, and acellular pertussis (DTaP))

for herpes zoster infection, 1703
pharmacokinetics of, 1706*t*
Famotidine, 1009, 1249*t*, 2220*t*
Fampridine, 1257

Fanapt (*see* Iloperidone)
Fansidar (*see* Sulfadoxine)
Fat-soluble vitamins, 473
for patients with CF, 477*t*
FCV (*see* Famciclovir (FCV))
Febuxostat, 948
drug interactions, 949*t*
Felbamate, 976*t*, 1317*t*, 1319, 1323*t*
Felodipine, for chronic stable angina pectoris, 225
Femring (*see* Estradiol acetate vaginal ring)
Femtrace (*see* Estradiol acetate tablet)
Fenofibrate, 128, 950
Fenofibric acids, 128
Fenoldopam (Corlopam), 353*t*
for BP, 359
for hypertensive crisis, 360
for hypertensive emergencies, 359
Fenoprofen, 905*t*
Fentanyl, 1217, 1219*t*
for opioid withdrawal syndrome, 1950
for pediatric intubation, 2257*t*
Feraheme (*see* Ferumoxytol)
Ferric carboxymaltose, for anemia, 2001
Ferric citrate, 651*t*
Ferric gluconate, for anemia, 2001
Ferritin, for anemia, 1999
Ferrous fumarate, for anemia, 1999
Ferrous gluconate, for anemia, 1999
Ferrous sulphate, 1296*t*
for anemia, 1999
Ferumoxytol, 644, 729
for anemia, 2001, 2002
Fesoterodine, 2314
Fexofenadine (Allegra), 133, 455*t*
for rhinitis, 458
Fibric acid, 128, 945*t*
adverse effects, 128–129
clinical pearls, 129–130
drug interactions, 129
efficacy, 127–128
mechanism of action, 127, 128*f*
pharmacokinetics/pharmacodynamics, 128
place in therapy, 129
Fibrinolytic therapy, 199
Fibronectin, 1024

Fidaxomicin (Dificid), 1372*t*
15-methyl prostaglandin $F2_{\alpha}$-tromethamine, 1030–1031
Finasteride, 2321
for BPH, 2321
for hirsutism, 1046
for prostate cancer, 2157
Fingolimod, 1255, 1262, 1262*t*
5-α-reductase inhibitors, 2157
5-aminosalicylic acid (5-ASA), 559
for Crohn disease, 562
5-flucytosine (5-FC), 1454, 1676
amphotericin B and, 1454
5-fluorouracil, 491*t*, 1667
5-HT_3 antagonists, for CINV, 493, 494*t*
Flagyl (*see* Metronidazole)
Flecainide
for AF, 333
for HF, 291
and PVC, 342
for WPW, 339
Flonase Sensimist (*see* Fluticasone furoate)
Floxin (*see* Ofloxacin)
Floxuridine, 491*t*
Fluconazole (Diflucan), 125*t*, 133, 976*t*, 1666–1669, 1676, 1676*t*, 1677, 1678*t*
adverse effects of, 1381*t*
for CAPD-associated peritonitis, 1533*t*
for chronic pulmonary blastomycosis, 1688
CNS penetration of, 1692
cryptococcal disease, 1695
dosing of, 1384*t*
for fungal endocarditis, 1454
for fungal infection, 1536
renal failure, dosing of drugs, 707
for sepsis, 2244*t*
for VVC, 1580*t*, 1581
Flucytosine, 1667, 1677
adverse effects of, 1381*t*, 1695
and creatinine clearance, 1695
cryptococcal disease, 1695
dosing of, 1384*t*
and GI distress, 1695
for OIs, 1656
renal excretion of, 1695
risk factor C, 1689
Fludarabine, 492*t*, 2048, 2054*t*

for CLL, 2087
encephalopathic toxicity of, 2049
neurotoxicity of, 2048*t*
Flumadine (*see* Rimantadine)
Flumazenil, 1813
hepatic encephalopathy, 584
for pediatric intubation, 2259*t*
FluMist, 1412
influenza vaccine, 1710
Flunisolide, 461*t*
for allergic rhinitis, 462
Fluorocytosine, 1676*t*
Fluorometholone acetate, 1202
Fluoropyrimidine, for colon cancer, 2126
Fluoroquinolones, 481, 509, 1424, 1605, 1788
and antacids, 41
for bacterial prostatitis, 1560
for *Campylobacter* infection, 1514
for CAP, 1466
for CAPD-associated peritonitis, 1530
for COPD, 442
for gonorrhea, 1565
for infectious diarrhea, 1504
for MAC, 1671
for nontyphoidal salmonellosis, 1508
for skin and soft tissue infections, 1605
for surgical procedures, 1393*t*
for UTI, 1547, 1549
for UTI in pediatric patients, 1554
Fluorouracil, 2038, 2042, 2043, 2043*t*, 2052
for adverse effects, 2127, 2132
and cerebellar dysfunction, 2048
for colon cancer, 2126
encephalopathic toxicity of, 2048
and hepatic dysfunction, 2056*t*
neurotoxicity of, 2048*t*
Fluoxetine (Prozac or Sarafem), 1808*t*, 1816, 1848
for bipolar depression, 1917
for depression, 2306
for depressive disorders, 1891*t*, 1892*t*
for OCD, 1829
for panic disorder, 1816
for PTSD, 1822
for Raynaud phenomenon, 179
and sleep, 1843

for vasomotor symptoms, 1069*t*
Fluphenazine, 1858*t*, 1868*t*, 1869*t*
decanoate, 1866*t*
for schizophrenia, 1864*t*
Flurazepam, 1840
and sleep, 1839
for treatment of insomnia, 1835*t*
Flurbiprofen, 905*t*
Flutamide, for prostate cancer, 2147
Fluticasone
for BPD, 2233
for chronic asthma, 415–416
for COPD, 439*t*, 441
for rhinitis, 462
Fluticasone furoate (Flonase Sensimist), 461*t*
for allergic rhinitis, 462
Fluticasone propionate (Dymista), 461*t*
for allergic rhinitis, 462
Fluvastatin, 47*t*, 57, 115*t*, 120, 121*t*, 125*t*
Fluvoxamine (Luvox), 1808*t*, 1816
for depression, 2306
for depressive disorders, 1891*t*
dosage, 1825
drug interaction with smoking, 1978*t*
for OCD, 1829
for PTSD, 1822
Fluvoxamine CR, for SAD, 1821
Fluzone High-Dose, 1412
Folate
alcohol withdrawal, 1968
for anemia, 2004
Folic acid, 977, 991
and pregnancy, 1000, 1011
recommended daily allowance (RDA), 1001
and women, 1001
Fondaparinux, 196, 261
for ACS, 249*t*
for DVT, 194
UFH and LMWH and, 183–184, 183*t*
Formoterol, for COPD, 438, 440
Fortaz (*see* Ceftazidime)
Fosamprenavir (FPV), 133, 945*t*
for HIV, 1640*t*
Fosaprepitant (Emend), 494*t*
Foscarnet (Foscavir), 775, 1666, 1700*t*, 1703

adverse effects of, 1381*t*, 1664, 1699*t*
dosing regimens, 1664
for herpes labialis, 1703
intravitreal administration, 1666
to prevent nephrotoxicity, 1664
Foscavir (*see* Foscarnet), 1700*t*
Fosfomycin, for UTI, 1543, 1544*t*, 1547
Fosinopril, 296, 296*t*
in hypertension, 160*t*
Fosphenytoin, 57, 976*t*, 1323*t*, 1330
in SE, 1340
for seizures, 1323*t*
FPV (*see* Fosamprenavir (FPV))
FreAmine HBC, 837*t*
FreAmine III, 837*t*
Frovatriptan, 1272, 1273
FTC (*see* Emtricitabine (FTC))
Furazolidone, for giardiasis, 1776
Furosemide, 576, 577, 623, 2053–2054
doses of, 292
for HF, 292
for hypercalcemia, 623*t*
for hypertension, 156
for nephrotic edema, 607
for PDA, 2234, 2237
urine osmolality and, 613

G

Gabapentin (Neurontin), 1220, 1228, 1234, 1257, 1277, 1310, 1310*t*, 1317*t*, 1319, 1916
androgen deprivation therapy, 2155
for diabetes, 1180
for PHN, 1705
for seizures, 1324*t*
for vasomotor symptoms, 1069*t*
Gabapentin, 1228*t*, 1324*t*
Gabapentinoids, 1228
Gabitril (*see* Tiagabine)
Gadolinium-based contrast (GBC) agents, 672
Galantamine
for Alzheimer disease, 2299
for vascular dementia, 2303
Gallium nitrate, for hypercalcemia, 623*t*
Gamma-glutamyl transferase (GGT), 1965

γ-Hydroxybutyric acid (GHB), 1953
Ganciclovir (Cytovene), 775, 776, 1666, 1700*t*
adverse effects of, 1382*t*, 1699*t*
for CMV disease, 1664
dose-limiting toxicity, 1664
dosing of, 1384*t*
ganciclovir-induced bone marrow suppression, 1664
for herpes simplex keratitis, 1204
induction dose of, 1664
intraocular implants, 1666
intravitreal administration, 1666
mode of administration, 1665
Ganciclovir-foscarnet combination, for CMV retinitis, 1665
Garamycin (*see* Gentamicin)
Gardasil, 1410
GBC agents (*see* Gadolinium-based contrast (GBC) agents)
Gefitinib, 492*t*
Gelclair, 2040
Gemcitabine (Gemzar), 491*t*, 2043*t*
for NSCLC, 2114*t*
Gemfibrozil, 125*t*, 127, 128, 128*t*, 129, 649
Gemifloxacin (Factive), 1373*t*
Gemzar (*see* Gemcitabine)
Gentamicin (Garamycin), 698, 701, 1201, 1372*t*, 1793
adverse effects of, 1379*t*
for bacterial endocarditis, 673, 674
for CAPD-associated peritonitis, 1533*t*
for chorioamnionitis, 1029
for CNS infections, 1426*t*
for cystic fibrosis, 482*t*
dosing of, 1384*t*
for enterococcal endocarditis, 1451*t*, 1452
for gram-negative aerobes, 1374*t*
for NEC, 2243
nephrotoxic antibiotic, 673
for UTI, 1553*t*
vancomycin and, 1452
Gentian violet, 1678
Geodon (*see* Ziprasidone)
GGT (*see* Gamma-glutamyl transferase (GGT))
GHB (*see* γ-Hydroxybutyric acid (GHB))
Ginger, for NVP, 1008*t*
Ginseng, 976*t*
Glargine, 1012
Glatiramer acetate, 1255

adverse effects of, 1258
patient characteristics and other factors associated with reduced adherence to, 1260*t*
patient counseling points for, 1260*t*
Gleevec (*see* Imatinib)
Glimepiride, 132, 1155, 1174
for type 2 diabetes, 1155, 1174
Glipizide, 132
for type 2 diabetes, 1155
GLP (*see* Glucagon-like peptide-1 agonists (GLP))
Glucagon, 721*t*, 1174
for hypoglycemia, 1141
Glucagon-like peptide-1 agonists (GLP)
adverse effects of, 1160
contraindications and precautions of, 1161
dosage and clinical use, 1162
drug interactions, 1161–1162
efficacy of, 1162
mechanism of action, 1159
pharmacokinetics of, 1159–1160
Glucarpidase, 2054
Glucocorticoids
antenatal administration, 1027
for fetal lung maturation, 1018
for NVP, 1008*t*
for prostate cancer, 2152
Glucomannan, 803*t*
Glucosamine, 901
Glucose, 618
for hyperkalemia, 620*t*
hypokalemia and, 615*t*
tablets for hypoglycemia, 1141
Glucosidase inhibitors
adverse effects of, 1158
contraindications and precautions of, 1158–1159
dosage and clinical use, 1160–1161
drug interactions, 1159
efficacy of, 1160
mechanism of action, 1158
pharmacokinetics of, 1158
Glutamine, 2048
Glutathione, 2048
Glyburide, 132, 709, 1013, 1034
for type 2 diabetes, 1155
Glycerol, 835

Glycoprotein IIb/IIIa inhibitors, 1356
Glycopyrrolate
for COPD, 439*t*
for end-of-life care, 92
Glycyrrhetinic acid, 2040
Gold, 914, 915
Golimumab, 915, 923, 926*t*
Gonadotropin-releasing hormone (GnRH) agonists, 1052–1053, 1053*t*
adverse effects, 1054
for depressive disorders, 1887*t*
for endometriosis, 1054–1055
Gonadotropin-releasing hormone (GnRH) analogs, for IVF, 994–996
Gonadotropin-releasing hormone (GnRH) therapy, for prostate cancer, 2141, 2146–2147
Goserelin (Zoladex), 1053*t*, 1054
Granisetron (Kytril), 494*t*
for PONV, 501*t*
Grastek, for allergic rhinitis, 457*t*
Grazoprevir, for HAV, 1752, 1753
Green tea, 803*t*
Griseofulvin, 976*t*, 1676, 1676*t*, 1678
risk factor C, 1689
Guanabenz, 167, 2325*t*
Guanfacine, 167, 2325*t*
for ADHD, 1940*t*, 1941
Guarana, 803*t*

mixing, 1132
monotherapy with type 2 diabetes, 1172–1173
pharmacodynamics of, 1115–1119, 1117*t*
pharmacokinetics of, 1115
premixed, 1173
stability, 1132
therapy, 1012
therapy, basal, 1173–1174
Insulin aspart (NovoLog), 1117
Insulin degludec (Tresiba), 1131
Insulin detemir (Levemir), 1012, 1131
Insulin glargine (Lantus), 1131
Insulin glulisine (Apidra), 1012, 1132
Insulin lispro (Humalog), 1117–1118
Interferon alpha, 491*t*
Interferons (IFNs)
for depressive disorders, 1887*t*
for HBV, 1738
Interleukin-2, for depressive disorders, 1887*t*
Intermezzo, for treatment of insomnia, 1835*t*
Intramuscular methylprednisolone, 955
Intranasal corticosteroids
for allergic rhinitis, 452
for rhinitis, 461–464, 461*t*
Intraocular ganciclovir implants, 1665
Intravenous (IV) albumin infusions, 577
Intravenous nitroglycerin, 315
Invanz (*see* Ertapenem)
Invega (*see* Paliperidone)
Iodines, 1678
and pregnancy, 1000
Iodoquinol, 1773
for amebic liver abscess, 1773*t*
for amebicides, 1773*t*
for gastrointestinal disease, 1773*t*
Iopidine (*see* Apraclonidine)
Ipilimumab, 492*t*, 2046
IPLEDGE program, 870

Ipratropium bromide (Atrovent), 461*t*
for allergic rhinitis, 453
for BPD, 2232
for COPD, 438, 439*t*
IPV (*see* Inactivated polio vaccine (IPV))
Irbesartan, for hypertension, 161*t*
Irinotecan, 491*t*, 2041, 2056
for adverse effects, 2132
for colon cancer, 2127
drug interaction with smoking, 1978*t*
for rhabdomyosarcoma, 2070
for SCLC, 2120*t*
Iron
for anemia, 1999
and dyspepsia, 509
GERD and, 526*t*
ingestion of, assessment of, 73–76
and pregnancy, 1000–1001
Iron dextran, 644
for anemia, 2001, 2002
injection, 729
Iron sucrose, 644
for anemia, 2001, 2002
Isavuconazole, 1676*t*
adverse effects of, 1381*t*
Isoflavone, 1063
Isoniazid, 505
and allergic reactions, 1490
dosing of, 1384*t*
drug interactions with, 1490
hepatotoxicity from, 1490–1491
for HIV-infected and TB, 1669
and peripheral neuropathy, 1491
for tuberculosis, 55, 56*t*, 1484*t*, 1488
Isoproterenol, 384*t*
GERD and, 526*t*
for postoperative cardiac failure, 384*t*
Isopto Carpine (*see* Pilocarpine)
Isosorbide, 1196
Isosorbide-5-mononitrate, 583
Isosorbide dinitrate (BiDil), 231, 312, 313
Isotretinoin, 976*t*
for acne, 870
teratogenic effects, 1004*t*
Isradipine, for chronic stable angina pectoris, 224

Itraconazole, 125*t*, 132, 505, 976*t*, 1667, 1676*t*, 1677, 1678*t*, 1679
adverse effects of, 1381*t*
antifungal agents, 41
for chronic pulmonary blastomycosis, 1689
CNS penetration of, 1692
dosing, 1679
for S. schenckii, 1679
IV antipseudomonal antibiotics, 483
IV colistin, 483
IV diltiazem, for AF, 364
IV methylprednisolone, 762
IV pentamidine isethionate, 1660
IV tobramycin, 483
IV verapamil, 364
Ivabradine (Corlanor), 286
Ivacaftor (Kalydeco), 63
Ivermectin, 1781
for lice, 1774*t*
Ixabepilone, 491*t*
peripheral nerve toxicity of, 2048
Ixazomib, 493*t*
Ixekizumab, 879
Ixempra (*see* Ixabepilone)

Kyleena, 982
Kytril (*see* Granisetron)

L

Labetalol (Normodyne; Trandate), 353*t*, 354*t*, 1017*t*, 1019
for BP, 354, 364
disadvantages of, 360
for hypertension, 166, 166*t*, 358, 361
parenteral to oral conversion, 360
for pregestational diabetes, 1011
Lacosamide, 1317*t*, 1319, 1324*t*
Lactogen, 1012
Lactulose, 2217*t*
hepatic encephalopathy, 585
and neomycin, 586–587
and rifaximin, 586
LAIV (*see* Live attenuated influenza vaccine)
Lamictal (*see* Lamotrigine)
Lamivudine, 1741, 1742
for HBV, 1740
for HIV, 1637*t*
in labor, 1029
Lamotrigine, 976*t*, 1227, 1228*t*, 1317*t*, 1319, 1324*t*, 1916, 1917, 1919*t*
for absence seizures, 1332
and carbamazepine, 1328–1329
for diabetes, 1180
for schizophrenia, 1881
for seizures, 1324*t*, 1328–1329
teratogenic effects, 1004*t*
Lansoprazole, 506*t*, 507, 525, 537*t*, 1249*t*, 2220*t*
Lanthanum, 651*t*
Lanthanum carbonate, 651–652
Lantus (*see* Insulin glargine)
Lapatinib, 133, 493*t*, 2052
L-asparaginase, 2079*t*
Lastacaft (*see* Alcaftadine)
Latanoprost (Xalatan), 1187
Latuda (*see* Lurasidone)
L-Carnitine, 176, 994
Lecithin, for RDS, 2227
Ledipasvir, for HAV, 1752, 1753
Leflunomide, 741, 745*t*, 746*t*, 914, 924

adverse effects, 922
and cholestyramine, 922
dosage, 922
Lenalidomide, 493*t*, 2048, 2054*t*, 2094
neurotoxicity of, 2048*t*
peripheral nerve toxicity of, 2048
Lenvatinib, 492*t*
Lepirudin, for heparin-induced thrombocytopenia, 185
Letrozole (aromatase inhibitor), 992, 1045*t*, 1046
Leucovorin, 2054, 2069
for *Toxoplasma* encephalitis, 1662–1663
Leukeran (*see* Chlorambucil)
Leukotriene
for allergic rhinitis, 452
for asthma, 417
modifiers, 480
for rhinitis, 464–465
Leuprolide (Lupron), 1053*t*, 1054
for prostate cancer, 2149
Levalbuterol, for COPD, 438, 439*t*
Levemir (*see* Insulin detemir)
Levetiracetam, 1219, 1317*t*, 1325*t*, 1916
for seizures, 1325*t*, 1328, 2251
Levobunolol (Betagan), 1187
Levocetirizine (Xyzal), 455*t*
for rhinitis, 458
Levodopa, 1286*t*
and adjunctive therapy, 1292
drug interactions, 1296*t*
metabolism in human body, 1295*f*
for Parkinson disease, 1289, 1295, 1301
for RLS, 1306
Levofloxacin (Levoquin), 514*t*, 1372*t*
for aerobic gram-positive cocci, 1373*t*
for CAPD-associated peritonitis, 1533*t*
for COPD, 442
dosing of, 1384*t*
for skin and soft tissue infections, 1606
for tuberculosis, 1485*t*
for UTI, 1544*t*, 1553*t*
Levomilnacipran
for depressive disorders, 1891*t*, 1892*t*
for serotonin, 1897
Levonorgestrel, 968–970*t*, 982
Levonorgestrel intrauterine system (IUS), 1049

Levonorgestrel-releasing IUD (Mirena), 982, 1065*t*
Levoquin (*see* Levofloxacin)
Levosimendan, 280
Levothyroxine (L-thyroxine), 91, 132, 976*t*, 1003, 1006, 1073–1074, 1075*t*, 1081
Lexapro (*see* Escitalopram)
Lialda (*see* Mesalamine)
Lidocaine, 1215*t*, 2040, 2189*t*
for cardiopulmonary arrest, 349–350
patches (Lidoderm), 1230, 1705
topical, 1705
for ventricular arrhythmias treatment, 258
Lidoderm (Lidocaine patches), 1705
Liletta, 982
Linaclotide (Linzess), 567
Linagliptin, 1162
Lindane, 1775*t*, 1780
toxicity, 1780
Linezolid (Tedizolid, Zyvox), 1372*t*, 1448
adverse effects of, 1380*t*
for aerobic gram-positive cocci, 1373*t*
for CAPD-associated peritonitis, 1533*t*
for CNS infections, 1426*t*
dosing of, 1385*t*
for endocarditis, 1450, 1453
for HAP, 1473
MRSA, 1606
for skin and soft tissue infections, 1604
with vancomycin, 1621
Linzess (*see* Linaclotide)
Lipid-lowering agents, 267
Lipopeptides, 1676
Liquid multivitamin, 477
Liraglutide (Saxenda), 801, 1159, 1173–1174
Lisdexamfetamine, for ADHD, 1940*t*
Lisinopril, 41, 296–297, 296*t*, 2286
in hypertension, 160*t*
for prostate cancer, 2143, 2150
Lispro, 1012
Lithium, 225, 622, 1907
and ACE inhibitors, 1914*t*
and acetazolamide, 1914*t*
and acne, 1912*t*
adverse effects, 1812*t*, 1911–1912
and antipsychotics, 1914*t*

for bipolar depression, 1917, 1919
for bipolar disorder, 1919*t*
and caffeine, 1914*t*
and carbamazepine, 1914*t*
for critically ill patients, 1241
for depressive disorders, 1889
and diltiazem, 1914*t*
and diuretics, 1914*t*
dosage, 1911
drug–drug interactions, 1914*t*
drug–food interactions, 1914*t*
half-life of, 1911
and hypothyroidism, 1913
and lactation, 1035*t*
and methyldopa, 1914*t*
monitoring of, 1911*t*
and NSAIDs, 1914*t*
patient education, 1912–1913
during pregnancy, 1913–1914
prelithium workup, 1911
psoriasis and, 872
for schizophrenia, 1881
and sodium, 1914*t*
and SSRIs, 1914*t*
teratogenic effects, 1004*t*
and theophylline, 1914*t*
toxicity, 1913
and verapamil, 1914*t*
weight gain with, 1913
Lithium carbonate, 1279
Lithium–lamotrigine, 1917
Live attenuated influenza vaccine (LAIV), 1412
LMWHs (*see* Low-molecular-weight heparins (LMWHs))
Local anesthetics, for neuropathic pain, 1214

Penicillin, 50, 976*t*, 1606
adverse effects of, 1379*t*
for aerobic gram-positive cocci, 1373*t*
allergy, 716
allergy skin testing, 717*t*
for anaerobes, 1375*t*
cross-reactivity between carbapenems and monobactams, 717
desensitization, 730
drug eruptions and, 863
for endocarditis, 1443
and hypokalemia, 615*t*
kidney failure, dosing of drugs, 706
for RMSF, 1794
for skin and soft tissue infections, 1603, 1606, 1608
for UTI, 1552*t*
Penicillin G, 1372*t*, 1447, 1788, 2189*t*
for CAPD-associated peritonitis, 1533*t*
for CNS infections, 1426*t*
dosing of, 1385*t*
for enterococcal endocarditis, 1451*t*
for GBS infection, 1028
for sepsis, 2244*t*
for syphilis, 1575*t*
Penicillin V, 1372*t*
Pentacel, 1407*t*
Pentamidine, 1660
Pentasa (*see* Mesalamine)
Pentobarbital, 2258*t*
Pentostatin, 491*t*, 2054*t*
Pentoxifylline, 175
for ASD, 1927
Peppermint oil capsules, 568
Peramivir (Rapivab), 1709

Perampanel, 1317*t*, 1319, 1325*t*
for seizures, 1325*t*
Perindopril, 160*t*
Permethrin, 1774*t*
liquid rinse, 1780
for scabies, 1775*t*
Perphenazine, 1306, 1858*t*, 1868*t*, 1869*t*
for schizophrenia, 1857, 1862
Pertuzumab, 492*t*
Petrolatum, 1780
P-glycoprotein/ABCBI inhibitors, 945*t*
Phenazopyridine, 1548
Phencyclidine (PCP), 1956
dissociative drug, 1956
and lactation, 1035*t*
for schizophrenia, 1853, 1853*t*
Phendimetrazine, 799
Phenelzine, 1817
Phenergan (*see* Promethazine)
Phenformin, 1174
Phenidone, 1035*t*
Pheniramine, 460*t*
Phenobarbital, 976*t*, 1317*t*, 1325*t*, 2189*t*
for febrile seizures, 1335
for opioid dependence, 1952
for SE, 1340
sedative-hypnotics, 1953
for seizures, 1325*t*, 2250–2251
Phenolates, 1678
Phenothiazines, 1858*t*, 2325*t*
for NVP, 1007, 1008*t*
Phenoxybenzamine, 2325*t*
Phentermine/topiramate (Qsymia), 762*t*, 799
Phentolamine, 2330
Phenylbutazone, 976*t* Phenytoin, 976*t*
Phenylephrine (Neo-Synephrine; Sudafed PE), 455*t*, 2267*t*
for postoperative cardiac failure, 384*t*
for rhinitis, 459
for septic shock, 393
Phenytoin, 41, 43, 57, 60, 505, 611, 1020, 1317*t*, 1323*t*, 2189*t*, 2279, 2325*t*
gum hyperplasia and, 1331
for HAV, 1752
hypersensitivity to, 1337–1338
initiation and dosage of, 1328
intoxication with, 1330

kidney failure, dosing of drugs, 708
neurotoxicity from, 1331
pharmacokinetics of, 1330
in SE, 1340
for seizures, 1323*t*, 1329–1330, 2251
teratogenic effects, 1004*t*
Phosphates, 28, 623*t*, 624
-binding agents, 651*t*
enema, 2217*t*
Phosphodiesterase inhibitors
androgen deprivation therapy, 2155
PDE-4, 878
PDE-5, 2328–2329

for febrile neutropenia, 1621

gentamicin and, 1452
high-risk medication, 658–659
for hypertension, 161*t*
kidney failure, dosing of drugs, 706–707
MRSA, 1606
for MRSA endocarditis, 1447–1450
for NEC, 2241
for PVE, 1446*t*
for sepsis, 2244*t*
for skin and soft tissue infections, 1604
for treatment of HF, 285
Valtrex (*see* Valacyclovir)
Vancocin (*see* Vancomycin)
Vancomycin (Vancocin), 481, 483, 1372*t*, 1793
for UTI, 1553*t*
Vandetanib, 493*t*
Vanillylmandelic acid (VMA), 2063
Vantin (*see* Cefpodoxime proxetil)
Vaqta, 1407
Vardenafil, 2329
and ED, 2329
Varenicline
adverse reactions, 1989–1990
for depressive disorders, 1887*t*
dosage, 1989
patient education, 1989
pharmacokinetics, 198
for smoking cessation, 1981, 1987
Varivax, 1414
Varubi (*see* Rolapitant)
Vascepa, 130
Vasodilators
for ACS, 257–258
for IC, 176
Vasopressin, 580, 2267*t*, 2269
for cardiopulmonary arrest, 350
for postoperative cardiac failure, 384*t*
for septic shock, 392
Vasopressin receptor antagonists (VRAs), 613
Vasotec IV (*see* Enalaprilat)
Vaxelis, 1407*t*
VCV (*see* Valacyclovir (VCV))
Vecuronium, 2259*t*
Vedolizumab
for CD, 560

for inflammatory bowel disease, 552*t*
for UC, 560, 563
Velban (*see* Vinblastine)
Velcade (*see* Bortezomib)
Vemurafenib, 493*t*
Venetoclax, 493*t*
Venlafaxine (Effexor, Effexor XR), 1228, 1273, 1280, 1808*t*
androgen deprivation therapy, 2155
for depressive disorders, 1891*t*
for panic disorder, 1816
for serotonin, 1897
for vasomotor symptoms, 1069*t*
Venlafaxine, 1229*t*
Venlafaxine ER, 1892*t*
Venlafaxine IR
for depressive disorders, 1892*t*
for hot flushes, 1069
Venlafaxine XR 1801*t*, 1808*t*, 1816, 1820
for PTSD, 1822
for SAD, 1820
Venofer (*see* Iron sucrose)
VePeSid (*see* Etoposide)
Verapamil, 125*t*, 133, 162, 176, 224, 642, 1093, 1279, 2325*t*
for AF, 333
for HF, 291
for HFpEF, 287
for thyroid storm, 1098
Vesanoid (*see* Tretinoin)
Vibativ (*see* Telavancin)
Viberzi (*see* Eluxadoline)
Vidarabine, 1701
for herpes encephalitis, 1698
Vigabatrin, 1317*t*, 1327*t*
Vilanterol, 438, 439*t*, 440
Vilazodone, 1898
for depressive disorders, 1891*t*, 1892*t*
Vinblastine, 492*t*, 2043*t*, 2056*t*
and autonomic neuropathy, 2049
and cranial neuropathies, 2049
gonadal toxicity of, 2059
neurotoxicity of, 2048*t*
peripheral nerve toxicity of, 2048
Vinca alkaloids, gonadal toxicity of, 2059
Vincristine, 492*t*, 2043*t*, 2049, 2065, 2093
and autonomic neuropathy, 2049, 2075

for HL, 2092
intrathecal, problems of, 2075
neurotoxicity of, 2048–2049, 2048*t*
peripheral nerve toxicity of, 2048
for rhabdomyosarcoma, 2070
for T-cell lymphomas, 2079*t*
Vinorelbine, 492*t*, 2043*t*
neurotoxicity of, 2048*t*
for NSCLC, 2114*t*
peripheral nerve toxicity of, 2048
Virazole (*see* Ribavirin)
Vismodegib, 493*t*
Vistaril (*see* Hydroxyzine)
Vistide (*see* Cidofovir)
Vitamin A
and pregnancy, 1001
teratogenic effects, 1004*t*
Vitamin B6 (*see* Pyridoxine)
Vitamin B_{12}, 524
for pernicious anemia, 2004
Vitamin C (*see* Ascorbic acid)
Vitamin D
calcitriol, 652
doxercalciferol, 653
for endometriosis, 1054
nutritional vitamin D, 652
paricalcitol, 653
and pregnancy, 1000
for pulmonary exacerbations, 474
receptor agonist, 652–653
Vitamin E, 994, 2048
for diabetic neuropathy, 2048
and pregnancy, 1000
for prostate cancer, 2157
Vitamin K
dependent clotting factors, 187*t*
and pregnancy, 1000
for pulmonary exacerbations, 474
supplementation in pregnant women, 1339
warfarin and, 203
VMA (*see* Vanillylmandelic acid (VMA))
Vorapaxar, 176, 254
for ACS, 251*t*
Voriconazole, 62, 125*t*, 132, 976*t*, 1626, 1676, 1676*t*, 1679, 1685, 1687, 1691
adverse effects, 1381*t*, 1691

dosing of, 1386*t*
Vorinostat, 493*t*
Vortioxetine, 1898
for depressive disorders, 1891*t*, 1892*t*
Votrient (*see* Pazopanib)
VPA (*see* Valproate)
Vraylar (*see* Cariprazine)

W

Warfarin, 41, 43–44, 57, 98, 132, 214, 976*t*, 1358*t*, 1359–1360
action of, 187*f*
adverse effects of, 201–202
alcohol ingestion and, 204
anticoagulant therapy, 199
and clotting factors, 1099
dosing adjustments, 204, 204*t*
drug interactions with, 212–215, 214*t*
effects of, 200*t*
factors influence, 202–204
frequency of follow-up, 204–205
genetic factors and, 203
hemorrhage from, 201
initiation dosing algorithm, 200*f*
intensity and duration of, 200–201
interactions with disease states, 203
international normalized ratio monitoring, 205*t*
overanticoagulation, management of, 205–206
in pregnancy, 206
protocol for, 200*t*
purple toe syndrome from, 201–202
skin necrosis from, 201
for stroke prophylaxis, 2303
teratogenic effects, 1004*t*
therapy, initiation of, 199–200
vitamin K and, 177, 187, 203

X

Xalatan (*see* Latanoprost)
Xanax (*see* Alprazolam)
Xanthine oxidase, and pregnancy, 1002
Xeloda (*see* Capecitabine)
Xerese (*see* Acyclovir and Hydrocortisone cream)
Xifaxan (*see* Rifaximin)

Xolair (*see* Omalizumab)
Xylometazoline, 455*t*
Xyzal (*see* Levocetirizine)

Y

Yerba mata, 803*t*
Yoga, 1056

Z

Zalcitabine, 2012
Zaleplon (Sonata), 1834
for treatment of insomnia, 1835*t*
Zanamivir (Relenza), 1469*t*, 1701*t*
adverse effects, 1699*t*
for influenza, 1709
pharmacokinetics of, 1707*t*
Zanosar (*see* Streptozocin)
ZDV (*see* Zidovudine (ZDV))
Zelapar (*see* Selegiline)
Zemplar (*see* Paricalcitol)
Zerbaxa (*see* Ceftolozane/tazobactam)
Zetonna (*see* Ciclesonide)
Z-hypnotics, 1837, 1846
Zidovudine (ZDV), 1029, 1638*t*
GERD and, 526*t*
for HIV-related anemia, 2012
Zileuton, 417
Zinacef (*see* Cefuroxime)
Zinc, 994, 1719
for gastroenteritis, 2218
and pregnancy, 1000
Zinc lozenges, 1719
Zinc oxide, 885*t*
Zioptan (*see* Tafluprost)
Ziprasidone (Geodon), 1306, 1809, 1868*t*, 1869*t*
for acute agitation, 1916
for acute mania, 1916, 1916*t*
for bipolar disorder, 1919*t*
for dyslipidemia, 1875
for hyperprolactinemia, 1874
for schizophrenia, 1857, 1859, 1861*t*, 1864, 1864*t*
Zithromax (*see* Azithromycin)
Ziv-aflibercept, 491*t*

for colon cancer, 2127, 2132
Zofran (*see* Ondansetron)
Zoladex (*see* Goserelin)
Zoledronic acid, 623*t*, 624, 2342, 2343, 2343*t*
androgen deprivation therapy, 2155
Zolinza (*see* Vorinostat)
Zolmitriptan, 1273, 1279
Zoloft (*see* Sertraline)
Zolpidem, 1837–1838, 1846
for sleep, 1932
for treatment of insomnia, 1835*t*
Zolpimist (*see* Mucous membrane spray)
Zomig (*see* Zolmitriptan)
Zonegran (*see* Zonisamide)
Zonisamide, 1317*t*, 1319, 1327*t*, 1916
for seizures, 1327*t*, 1328
Zostavax (*see* Zoster vaccine)
Zoster vaccine (Zostavax), 1414
Zosyn (*see* Piperacillin-tazobactam)
Zovirax (*see* Acyclovir (ACV))
Zyprexa (*see* Olanzapine)
Zyrtec (*see* Cetirizine)
Zyvox (*see* Linezolid)

Action potential duration (APD), 326
Action to Control Cardiovascular Risk in Diabetes (ACCORD), 641, 1110
-Blood Pressure (ACCORD-BP) trial, 145
Activated charcoal, use of, 68–69, 80
Activated partial thromboplastin time (aPTT), 36, 183, 189, 1368
Active disease, TB and, 1478–1479
treatment of, 1482–1489, 1483*t*
Active oligoarthritis, 931
Active polyarthritis, 930–931
Activities of daily living (ADLs), 900
Actual body weight (ABW), 190
ACUITY trial (*See* Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial)
Acupuncture, 465
Acute asthma, 405–413

β_2-adrenergic agonist therapy, 407–412
corticosteroid therapy, 412
goals of therapy, 405–407
respiratory failure and, 412
Acute bleeding, treatment, 581*t*
Acute bronchitis (AB), 1459–1460
causative organism, 1459
clinical diagnosis of, 1459–1460
clinical presentation of, 1459
definition of, 1459
drug therapy for, 1459
epidemiology of, 1459
incidence of, 1459
microbiology of, 1459
pathophysiology of, 1459
patient education, 1460
treatment of, 1459–1460
Acute care setting, medication therapy management services in, 13–14
Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial, 264
Acute cellular rejection, 767
Acute CF exacerbations, 485
Acute cholangitis, 1525–1528
Acute cholecystitis, 1525–1528
clinical presentation/diagnosis of, 1527
definition of, 1526
etiology of, 1527–1528
treatment of, 1528
Acute coronary syndrome (ACS), 154, 220, 241
algorithm for, 243*f*
cardiac biomarker elevation in, 243*f*
clinical presentation of, 241–242, 258–260
anterior vs. inferior infarction, 259
laboratory abnormalities, 259
risk stratification, 259–260
STEMI and NSTEMI, 259
therapeutic objectives, 259–260
complications of, 245
diagnosis of, 242
epidemiology of, 241
hallmark symptoms for, 241–242
laboratory changes in, 242–243
lifestyle modifications, 272
pathophysiology of, 241
pharmacotherapies for, 246–251*t*

risk stratification of, 244–245, 244*t*
thrombus formation and, 242*f*
Acute cystitis, 1009–1010
Acute decompensated heart failure (ADHF), 280
Acute exacerbation of chronic obstructive pulmonary disease (AECOPD), 1460–1462
clinical presentation of, 1461
definition of, 1460
diagnosis of, 1461
epidemiology of, 1460
pathophysiology of, 1460–1461
severity of, 1461
treatment for, 14611462
Acute glomerulopathies, 669–670
poststreptococcal, 669–670
rapidly progressive, 670
Acute gut inflammation, 1241
Acute headaches, 1269–1270
Acute heart failure, hemodynamic profile of, 314*f*
Acute hemorrhagic shock
causes of, 373
hypertonic saline for, 376
treatment of, 373–377
Acute interstitial nephritis (AIN), 674–675
Acute kidney injury (AKI), 661–679
biomarkers, 665
causes of, 663*t*
clinical course, 670
crystal-induced, 675
drug dosing in, 676–677
definition of, 661–662
epidemiology of, 662
functional, 663*t*
history and physical examination in, 664
intrinsic, 663*t*, 669–676
clinical significance of urinary sediment in, 666*t*
laboratory evaluation in, 664–667, 666*t*
pathogenesis of, 662–664, 663*t*, 664*f*
phases of
diuretic phase, 670
oliguric phase, 670
recovery phase, 670
postrenal, 663*t*
angiotensin receptor blocker-induced, 668–669, 668*f*
prerenal and functional AKI, 667–669

prognosis for, 662
supportive management of, 675–679, 678*f*, 678*t*
tubulointerstitial diseases and, 670–671, 671*f*
urinalysis and, 665–666, 666*t*
urinary sediments and, 666*t*
Acute liver failure (ALF)
and HBV, 1731–1732
primary therapy for, 1732
Acute lung injury (ALI), 817
Acute lymphoblastic leukemia (ALL), 2071–2078
age factor, 2071
B-cell lineage, 2072
and bone marrow blasts, 2072
clinical presentation of, 2070–2071
clinical variables, 2072
cytogenetic subtypes of, 2071
cytogenetic variables, 2072
diagnosis of, 2071–2072
early response, 2072–2073
epidemiology of, 2071
etiology of, 2071
immunologic variables, 2072
incidence rate, 2071
minimal residual disease (MRD) in bone marrow samples, 2072–2073
pathophysiology of, 2071
Philadelphia chromosome, 2072
prognostic factors, 2072–2073
racial and ethnic differences, 2071
relapsed, 2077–2078
signs and symptoms, 2071
T-cell lineage, 2072
treatment
CNS preventive therapy, 2074
intrathecal methotrexate dose, 2075
IT chemotherapy, 2074–2075
maintenance, 2075–2077
postinduction chemotherapy, 2075
remission induction therapy, 2073–2074, 2074*t*
with vincristine, 2075
WBC count, 2072
Acute myeloid leukemia (AML)
chromosomal abnormalities, 2084
classification of, 2083–2084
clinical presentation of, 2083
diagnosis of, 2083–2084

definitive diagnosis, 2083
in elderly, 2087
overview of, 2083
pathophysiology of, 2083, 2084*t*
refractory or resistant, 2087
signs and symptoms, 2084
translocations in, 2084
treatment, 2084–2085
chemotherapy, 2086–2087
induction chemotherapy, 2085–2086
postremission therapy, 2086–2087
Acute myocardial infarction (AMI), 241, 383
complications of, 245
goals of therapy, 381–382
Acute otitis media (AOM), 2221–2222
Acute pain, 1210
Acute pancreatitis, 844
Acute pharyngitis, 2222, 2223*t*
Acute pulmonary exacerbation, 475, 481–485
antibiotic dosing, 481–483
antibiotic drug selection, 481
chronic maintenance therapy, 483–485

Hyperkalemia, 23, 576, 617–619, 642–643, 676
and ACEI, 300–301

causes of, 301*t*
clinical manifestations of, 618
etiology of, 617–618
occurrence of, 377
treatment of, 618–619, 620*t*
Hyperlipidemia, 219, 228, 655
posttransplant, 771
Hypermagnesemia, 27, 630–631
clinical manifestations of, 630
etiology of, 630
treatment of, 630–631
Hypernatremia, 22, 614
diarrhea and, 22
fluids and, 22
Hyperosmolar hyperglycemic state (HHS), 1175
Hyperparathyroidism, 649
Hyperphosphatemia, 28, 628, 649
Hyperprolactinemia, 1040
in patients with schizophrenia, 1874
Hyperreactivity
defined, 400
measurement of, 400
Hypersensitivity reactions, from heparin, 193
Hypersensitivity vasculitis, 723, 723*t*
Hypertension
posttransplant, 771
Hypertension, Abnormal renal or liver function, Stroke, Bleeding, Labile INR, Elderly, Drugs and alcohol (HAS-BLED), 201
Hypertension (HTN), 647–648
alcohol and, 146
in ambulatory older patients, 2285
antihypertensive therapy, 648
associated with anticancer therapies, 2052
with bevacizumab, 2025*t*, 2052, 2135
black patients and, 152
blood pressure and, 141
chronic kidney disease and, 149, 154
and cigarette smoking, 1987
clevidipine for, 363
clinical evaluation of, 148–149
complications associated with, 145*t*, 148–149
and contraception, 966
coronary artery disease and, 154
in depression, 1885
with dexamethasone use, 2233

diabetes and, 153–154, 1176–1177
dialysis, 647–648
with doxazosin, 2320
with doxorubicin, 2049–2052
with ED, 2324
in elderly patients, 152–153, 2285
enalaprilat for, 363
essential, 140–168
HF and, 277
in ICU, 1238
inadequate BP control, reasons for, 158–159, 159*t*
intracranial, 2272–2273
labetalol for, 361–362
left ventricular dysfunction and, 154
and lithium, 1912
management of, 144–148, 151–155, 173–174
  goals in, 144–145
  lifestyle modifications for, 145–146, 151
and neuroblastoma, 2063
nicardipine for, 363
ocular, 1185
orthostatic, 152
pain and, 1225
with pazopanib, 2027*t*, 2052
pharmacotherapy for, 146–148, 151–154, 153*t*
physical activity and, 146
potassium and, 146, 156–158
in pregnancy, 1015, 1018–1019
  chronic, 1015, 1018–1019
  treatment of, 1018–1019
pulmonary, 2232, 2265
pulmonary arterial, 276
renin, 2063, 2066
resistant, 163–165
secondary, 143–144*t*
sodium and, 145–146
with sorafenib, 2052
systemic, 2234, 2272–2273
treatment of
  benefits of, 150–151
  goals in, 150
  patient education in, 150, 150*t*, 156
two-drug regimens for, 159
type 2 diabetes mellitus and, 1108*t*
types of, 143–144

with VEGF receptor inhibitors, 2052
white-coat, 143–144
Hypertension in the Very Elderly Trial (HYVET), 144–145, 152–153
Hypertensive crises, 144
defined, 351
management for, 355*f*
Hypertensive emergency
aortic dissection, 364–365
assessment of, 358–359
central nervous system and, 352
clinical presentation of, 352
defined, 351
fenoldopam for, 360–361
medications for, 353–354*t*
oral vs. parenteral therapy, 352–355
parenteral drug therapy, 359–364
treatment recommendations for, 356*t*
vs. urgency, 352*t*
Hypertensive urgency, 351
assessment of, 356–357
clinical presentation of, 352
medications for, 354*t*
oral drug therapy, 357–358
oral vs. parenteral therapy, 352–355
treatment of, 352–356
vs. emergency, 352*t*
Hyperthermia
by drug overdoses, 78
from salicylate toxicity, 72
in serotonin syndrome, 1897
in SIRS, 2264
Hyperthyroidism, 1806*t*, 2323
causes of, 1074, 1075*t*
clinical presentation of, 1089
iodide therapy, 1089–1090
laboratory findings, 1075*t*
in pregnancy, 1095–1096
prevalence of, 1072
treatment, 1074, 1090–1091*t*, 1090–1095
T2 thyrotoxicosis, 1099
Hypertrichosis, 167–168
Hypertriglyceridemia
and peripheral arterial disease, 169
and postmenopausal hormone therapy, 1065*t*
Hypertrophic osteoarthropathy, 474

Hyperuricemia, 665
asymptomatic, 951
and diuretics, 293
drug-induced, 947
treatment, 944–947, 945*t*
urate-lowering therapy, 947
Hyperventilation, for TCA toxicity, 80
Hyphae (molds), 1674*t*
Hypnosis, 1236*t*
Hypoalbuminemia, 698
Hypoalphalipoproteinemia, 110*t*, 112
Hypocalcemia, 621–622, 649, 2249–2250
clinical manifestations of, 621
etiology of, 621
treatment of, 621–622
Hypochloremia, 23
Hypoglycemia (*See also* Type 1 diabetes)
causes of, 1135
level 3, 1140
level 1 and 2, 1140
nocturnal, 1135, 1138
pathophysiology of, 1138–1139
preprandial, 1133
risk of, 1134
symptoms of, 1135, 1139
treatment of, 1139–1140
Hypogonadism, 2354
Hypokalemia, 23, 158, 615–617, 1685
clinical manifestations of, 616
and diuretics, 293
drugs inducing, 615*t*
etiology of, 615–616, 615*t*
PN and, 845–846
treatment of, 616–617
Hypomagnesemia, 27, 628–630, 1685, 2249–225
clinical manifestations of, 629
and diuretics, 293
etiology of, 628–629
PN and, 846
treatment of, 629–630
Hyponatremia, 18, 22, 575, 576
brain adaptation to, 608–609
clinical presentation and treatment of, 609*t*
and diuretics, 293
euvolemic hypotonic, 611–612

hypervolemic hypotonic, 610–611
hypotonic, with decreased extracellular fluid, 610
management of, 613
neurologic manifestations of, 608
normovolemic hypotonic, 611–612
rate of correction of, 612
Hypoperfusion, 370
Hypophosphatemia, 28, 626–628
clinical manifestations of, 626–627
etiology of, 626
PN and, 846
treatment of, 627–628
Hypopnea, 1846
Hypotension
intradialytic, 689–690
schizophrenia in, 1873
Hypothalamic-pituitary-adrenal (HPA), 414
Hypothalamus dysregulation and obesity, 795
Hypothermia, 49
Hypothyroidism, 2216, 2323
in bipolar disorder, 1913
with cardiac disease, 1087–1088
clinical presentation of, 1081
fetal, 1095–1096
and goiter, 1072
iatrogenic, 1096–1097
laboratory findings, 1074*t*
subclinical, 1088
thyroid hormone therapy for, 1081–1086
treatment, 1074*t*
Hypovolemia, 580
causes of, 378
postoperative bleeding and, 378
vs. pump failure, 377–378
Hypovolemic shock
acute hemorrhagic shock, 373–377
bleeding and, 373
defined, 372
Frank-Starling mechanism, 378
hypothermia and, 378
postoperative hypovolemia, 377–379
Hypoxic ischemic encephalopathy, 2249
Hysterectomy, prophylaxis for, 1394*t*
